Earthworks Risk Assessment on a Heritage Railway

Accepted for publication in Proceedings of the ICE Geotechnical Engineering on 19th March 2013

Abstract
The UK is home to a substantial number of heritage and tourist railways which make a significant contribution to their local economies. These are mostly constructed on the routes of closed lines, and include large numbers of earthworks of uncertain construction and unknown strength. Recently, there have been earthwork collapses, most notably on the Gloucester and Warwickshire Railway during 2010 and 2011. The Office of Rail Regulation has also noted a number of safety incidents on heritage railways, all attributable to management failures. This paper describes an analysis of the Victorian earthworks on the Bo’ness and Kinneil Railway, a five-mile long heritage railway in central Scotland. The analysis and risk prioritization method used by Network Rail was found to be unsuitable for direct application to heritage railways due to the different operating context. A new system was therefore developed, removing some risk factors from the Network Rail approach, adding others and modifying further ones. The new system was successfully applied and the Bo’ness and Kinneil Railway earthworks were found to be generally stable and safe.

Introduction – Safety Risks on UK Heritage Railways
In times when there is much talk of High Speed Rail, it is worth considering that the UK is home to a significant industry based on low speed rail – the heritage and tourist sector. There are currently over 100 heritage railways (HRs), employing 2,000 paid staff, 18,000 volunteers, carrying 6.8 million passengers on 15 million passenger journeys, turning over £84 million and contributing an estimated £579 million to the UK economy (Lord Faulkner 2011).

Being passenger carrying railways, HRs are subject to exactly the same requirements for safety as any other passenger railway, though they are generally restricted to speeds of 25mph or less. Whilst they have much lower annual tonnages of traffic than the main line system, they use historic steam and diesel locomotives, and consequently their axle loads can be relatively high, typically of the order of 25 tons. In most cases, heritage railways occupy track beds formerly part of the national rail network, often branch lines closed in the “Beeching Cuts” – the substantial reduction of the UK rail network carried out while Dr Richard Beeching was chairman of British Rail in the 1960s (British Railways Board 1963a) (British Railways Board 1963b). In common with the rest of the UK network, their infrastructure often dates from a time when there was relatively little theoretical understanding, design or quality control, and typically no records exist either of construction or of maintenance. Further, whilst HRs sometimes rely on a core of paid employees, they
are generally staffed by volunteer enthusiasts who come from a wide range of backgrounds and in many cases do not have either long experience or formal technical qualifications.

The UK HR sector has a good record of safety. From 1951 to 2010 there was a year-on-year reduction in safety incidents. However over the two years after that there was a significant reversal, with reportable incidents on over twenty railways, some staff fatalities and eight Office of Rail Regulation (ORR) enforcement notices, all of which are traceable to failings in the management structure of heritage railways (Keay 2012). The ORR regards this as so serious that special seminars were arranged via the Heritage Railway Association in an attempt to prevent further accidents.

There have also been notable failures of earthworks. The Severn Valley Railway (SVR) was subject to a series of major earthwork failures following abnormally high rainfall events in June and July 2007, costing £3.7 million to repair (Sowden 2012), whilst the Gloucester and Warwickshire Railway (G&WR), which occupies a 10 mile former British Railways (BR) route between Toddington and Cheltenham Racecourse in central England, experienced two severe slips, at Gotherington in April 2010 and at Chicken Curve near Winchcombe in early 2011. Both slips occurred in embankments where drainage was an issue and which had given trouble and required on-going maintenance in BR days and before (see http://www.gwst.com). Fortunately, neither the SVR nor the G&WR incidents led to loss of life.

**The Bo’ness and Kinneil Railway**

The Bo’ness and Kinneil Railway (B&KR) (see [http://www.bkrailway.co.uk](http://www.bkrailway.co.uk)) is a five mile HR running from Bo’ness to a junction with the Network Rail (NR) Edinburgh & Glasgow main line. The HR was opened in stages from the early 1980s, but occupies the line of the Slammanan and Borrowstounness (Bo’ness) Railway opened in 1851. A map showing the location of the railway is included in Figure 1.

For one and a half miles of its length, the line occupies the side of a steep escarpment close to the Forth Estuary between Bo’ness and Grangemouth, with the track supported on the north side by steep earth embankments, typically 15m high, and cut on the south side by soil and in some places rock slopes up to 10m high. (Figure 2). Thereafter the line turns south, passing through some moderately deep cuttings and over two further sections of embankment before reaching the mainline junction at Manuel.

All the earth and rock structures have been subject to somewhat irregular, but reasonably frequent inspections by Independent Competent Persons (ie qualified permanent way/engineering staff not having a direct interest in the Railway), including in March 2010 and May 2011, and are considered safe. However, they are almost all heavily vegetated, occasionally subject to animal burrowing and generally wet. No details of their construction or historic maintenance survive, though there is evidence of past failure due to washout in places and at one point the installation of a pipeline has led to a reconstruction. It cannot therefore be claimed that they represent a zero risk.

Any failure of the B&KR earthworks, in addition to putting passengers and railway staff at risk, would have a very serious impact on business: apart from the heritage passenger trains, access is required to the mainline junction for movements of rail tour coaching stock, which brings in considerable revenue to the line’s owners.
In view of this, and bearing in mind the events described at the SVR and G&WR, together with the ORR’s concerns with management structures for safety, it has been determined that a proper risk-based assessment procedure is appropriate for the B&KR earthworks. The assessment procedure has to be commensurate with the HR operation, based on HR safety and business priorities and bearing in mind the volunteer staff who will operate it and the low speed, low traffic and low resource availability context of the B&KR and HR sector in general.

The aim of this study was therefore to develop a risk assessment procedure for earthworks that is applicable to the HR sector bearing in mind its nature; and to apply this to the B&KR and use it to determine any monitoring or remedial actions necessary.

**Previous Work on Earthworks Risk Assessment**

**The Bo’ness and Kinneil Railway**

Recent inspection reports by independent competent persons have noted that the B&KR earthworks “appear generally stable,” whilst noting the presence of mature slips and other minor issues (Watson 2010; Watson 2011). There is however currently no prioritization of inspection or maintenance activity on the B&KR and previous interventions have largely been reactive to incidents or perceived problems.

**Network Rail**

NR employs a risk-based approach to the prioritization of earthworks. This is a two-stage process, commencing with an analysis and scoring of the geotechnical hazard of various types failure. These geotechnical hazard scores are then converted to a *likelihood of failure* score and used in a prioritization algorithm that combines it with various potential consequences of failure. The process is explained in more detail in the following paragraphs.

**Geotechnical Hazard**

For earth slopes, NR uses the Soil Slope Hazard Index (SSHI) (Manley and Harding 2003). The entire network is divided into five chain (approximately 100m) lengths and each side of the railway is considered separately. A site inspection is carried out by a trained operative who examines over 30 separate parameters covering earthwork type, size and shape, vegetation and drainage as well as indicators of on-going or potential failure such as tension cracks, angled trees, presence of animal burrows, and other risk factors such as a history of track misalignment, past interventions or mining in the area. The values noted against the various factors are recorded using a Trimble™ hand-held computer with an inbuilt camera for photographing observations.

The observed parameters are then fed into an algorithm derived by (Manley and Harding 2003) to determine the SSHI. This accounts for five principal mechanisms in which earthworks can fail: rotational, translational, earthflow, washout and burrowing, and scores each section inspected for each of these mechanisms; the highest geotechnical hazard score (ie highest risk score) obtained is used to classify an individual 100m length as either serviceable, marginal, or poor for the failure mechanism to which the score corresponds.

For rock slopes, a related process is used to assess the stability of the rock, based on the Rail Rock Slope Risk Appraisal (RRSRA) (McMillan and Manley 2003).
Poor slopes are then re-inspected at least every two years, marginal every five years and serviceable every ten years.

**Prioritization Calculation**

Having determined the numerical geotechnical hazard score, this is then fed into a more general prioritization algorithm derived by (Mott MacDonald and Network Rail 2006). This algorithm considers the likelihood and consequences of different potential failure mechanisms against four categories weighted for their relative significance, as shown in Table 1. These categories are Safety, Value for Money, Disruption and Environment.

In addition to the geotechnical hazard, a variety of other factors contribute to these consequences, including track condition and significance of temporary speed restrictions (TSRs), track layout (straight, curved or switches and crossings), geographical weather risk, past failures, route speed, potential delay costs and the availability of alternative routes. Some of these are assessed on site and some by means of a desk study, but all must be determined for each five chain length of one side of the railway.

Each factor contributes to some or all of the various consequences based on a relative scoring scheme, developed through a wide-ranging consultation and testing exercise by (Mott MacDonald and Network Rail 2006) (see
Table 2). For example, in terms of the geotechnical failure mode, potential rockfall and washout failures count for 24 (high risk) against all four consequence categories, whereas burrowing and earthflow count for 13 and 11 respectively (lower risk). Cuttings are scored at 18, a greater risk than embankments at 14. On the other hand, route speed contributes only to safety and disruption and not to value for money or environment, with (obviously) higher speeds scoring a higher number of risk points than lower ones (2 for 0-79, mph, 5 for 80-99mph, 8 for 100-110mph and 9 for 111-125mph).

The risk points scored by each parameter against each consequence category are summed and the total multiplied by the weighting of the consequence category (Table 1). The four products are then summed to determine a total prioritization score. The highest score is taken as the highest risk priority for monitoring and engineering intervention. Full details of the original NR consequence scoring are included in
This risk-based analysis has passed its accreditation process, it is credible to senior earthwork engineers and has been used by NR for a decade. In 2008, following three separate incidents involving earthworks failures, an investigation by the Rail Accident Investigation Branch (RAIB) concluded that the SSHI algorithm as adopted by Network Rail was technically sound whilst noting a number of issues regarding its implementation, principally related to variations in practices in different localities and the lack of a significant number of data points (ie earthwork-related incidents) to form a scientific judgement (RAIB 2008).

Assessing the Bo’ness and Kinneil Railway
The NR approach was the obvious starting point for a logical and complete assessment of the B&KR earthworks. However, the NR methodology had to be adapted since access to the Trimble™ or indeed any hand-held computer was not possible. The parameters were therefore set out on a paper questionnaire, exactly as in the original NR scheme. The first one and a half miles of railway from Bo’ness station to where it passes under the main Bo’ness – Grangemouth road is on flat land (the foreshore area) with no earthworks present, so this section was excluded from the study. The remainder of the railway was divided into 114 sections of length approximately 100m, each section being one side of the railway only.

A questionnaire was filled in for each section. Questions to do with underlying geology and adjacent catchment area were answered by means of a preliminary desk study, the remainder being addressed on site during two visits to the line on 21 November and 5 December 2011, when engineering possessions and associated protection arrangements ensured that there was no safety risk from train movements. Subsequently the responses were transferred to a spreadsheet which was in turn programmed to implement the SSHI algorithm and the prioritization process.

Initial Results and Discussion
The completion of the analysis, particularly filling in the questionnaire at the line side, is a process which clearly requires training. In this instance the authors carrying out the work were final year undergraduate MEng Civil Engineering students. They took some time to get used to the process but thereafter found the completion of the questionnaires to be relatively straightforward based on geotechnical engineering knowledge acquired during the preceding years of their degree programme.

SSHI Results
The SSHI (ie the geotechnic hazard) results are summarized in
Table 3. Of the poor slopes, most were cutting slopes (ie above rail level) on the south side of the railway, with some being cutting slopes located south of Birkhill Station, on both sides of the railway. Only a few were embankment slopes (below rail level) located near where the railway turns south away from the Forth estuary. A variety of potential failure modes were exhibited, with some of the high, steep embankment slopes giving indications of rotational and translational failure, and some of the cutting slopes appearing additionally vulnerable to washout and earth flow type failures.

It is stressed that a result of poor does not mean that the earthwork presents an immediate safety hazard; it is rather an indication that monitoring is needed on at least a biennial basis to avoid a risk developing.

Initial Prioritization
In order to prioritize possible interventions on the B&KR earthworks, the prioritization toolkit was applied using all the original NR scheme unaltered. The main results of this analysis are shown in Figure 3, in which the prioritization of earthworks is indicated by the large boxed numbers, with 1 indicating the earthwork section with the highest priority for monitoring and possible intervention. Some areas have equal priority, and thus the same number appears twice; the priorities shown are not all consecutively numbered, as some of the priorities between 1 and 17 were on sections of the railway not covered by the figure.

In this result, the top priority is at a location where there has been previous disturbance due to excavation for an oil pipeline crossing in the 1980s, and the consequence includes possible impact on the pipeline. This therefore appears to make sense. However, many of the next priorities are cutting sides on the south side of the railway. Applying engineering judgement, the prioritization of these areas makes much less sense, since examination on site, together with the experience of some small past failures suggested that the cutting sides could collapse with no significant consequence to third parties, the being only woodland or agricultural land on the top side of the cutting. There is also a wide area by the line side to accommodate any debris, and if any debris did fall on the rails, the visibility for train crews was generally sufficient to achieve a controlled stop in the distance available given the 20mph maximum line speed in the area.

On the other hand, the embankment slopes given the 10th, 13th, 15th and 17th priorities had poor SSHIs and engineering judgement suggested that any failure here could have major impact on the railway. This would include undermining the track formation, severing the line and causing all income-generating operations to cease, as well as presenting a safety risk to trains and in some cases to owners of domestic property positioned below the railway.

In view of this it was decided to re-assess the prioritization approach in the light of needs specific to HR operation. This was done with the assistance of a focus group consisting of ex-NR civil engineers, currently practising independent competent persons with both NR and HR experience and civil engineers with earthwork experience outwith the rail environment.

Adapting NR Risk Weightings to HRs
A number of issues were found when applying the NR prioritization in an HR context. In terms of the four generic consequence categories (Table 1), the presence of environmental appeared to be over-emphasised for HRs. This is not to say that HRs do not take environmental impact seriously, but in general this impact is probably low, and is strongly linked with factors such as tourism and traffic to access their stations. Thus, use of
environmental as a consequence category is unlikely to make significant distinction between priorities for earthwork monitoring or intervention. In the NR system, as well as environmental being a consequence category (Table 1), environmental obligations is a parameter considered under legal obligations (}
Table 2) and it was felt that its presence here was sufficient for HRs without including it as a separate consequence category as well.

Further, the value for money consequence was thought to be too complex and was therefore simplified to financial, covering the actual cost of repair of a damaged earthwork. Disruption was also modified, since detail such as delay minutes is less relevant to HR operations as no fines are payable to Train Operating Companies. Instead, disruption was used to consider indirect costs such as loss of income, the inability to run trains (including engineering trains) and impacts on reputation of the individual railway or the HR movement in general.

Accordingly the consequence categories were re-defined for use on HRs as shown in Table 4.

The prioritization scoring factors used by NR (
Table 2) then needed to be adapted to the new consequence categories shown in Table 4. Further issues were also identified with the prioritization scoring factors, as described in the following sections.

**Geotechnical Information**

NR prioritizes cuttings over embankments for statistical reasons, as more accidents have occurred due to cutting failure (RAIB 2008). For similar reasons, rock-falls and washouts are given a higher priority over other types of failure. However, these statistics, derived from NR operations, will not necessarily have any bearing on HR operations where conditions and in particular line speeds are very different, so (unless further information becomes available in the future) it was thought more appropriate to consider all these factors equally. NR also uses a geotechnical engineer’s assessment of earthwork (and rock slope) condition and trend as part of the geotechnical scoring, and this is unlikely to be generally available to many HRs which do not have geotechnical specialists available to make routine assessments.

**Track condition**

NR considers track condition, including geometry, trends and risks of temporary speed restrictions (TSRs) with impact on train operating companies (TOCs) in its risk assessment; however, these factors are less relevant to HRs. Track condition is likely to be generally poorer than mainline standards but matters less at low line speeds, and the financial penalties of a TSR are also not relevant when line speed limits are always less than 25 mph.

**Consequence Potential**

In this general category, the NR system considers route sensitivity, which covers the availability of a diversion for through traffic. This is clearly irrelevant to HRs. Route speed, flexibility of wrong-line running on multiple tracks and potential delay payments to TOCs are also not relevant.

**Other Projects**

Though not irrelevant, the treatment of opportunities and drivers associated with other projects were thought to be overly complex for HR implementation and suitable for simplification.

On the other hand, it was considered that there were a number of factors relevant to HRs that were not included in the NR system. These are as follows.

**Site Access**

On the B&KR, and many other heritage railways, access for plant and personnel to repair a damaged earthwork, particularly if the railway itself was no longer passable, would be a serious issue. This was, in fact, a notable issue in the repairs to the SVR after the 2007 flooding (Sowden 2012). It is therefore more important to maintain difficult-to-access earthworks in a serviceable state than is the case for the more accessible ones.

**Detectability of Failure**

A key issue for HRs is the likelihood of incipient failure being detected; this will have a clear impact on the safety consequence, and is likely to be more variable on HRs relying on volunteer staff with diverse responsibilities, as opposed to NR where there is a clearly set out inspection programme with dedicated staff to administer it. Some earthworks and rock slopes will be more frequently observed, for example those near staffed stations, whereas
features in more remote locations, where there is heavy vegetation or features above cutting horizons, are less likely to be noticed. It was thought that this variability should be included in a risk assessment for HRs.

**Shared Responsibility**
This factor was added to account for situations such as the pipeline crossing on the B&KR where the earthwork, and consequently any repairs, would be a shared responsibility with the pipeline operators. In general this will apply in many HR contexts such as where the earthwork supports a highway bridge structure or adjacent road.

**New Prioritization for the B&KR**
In view of the foregoing discussion, a revised prioritization scoring against the new consequence categories (Table 4) was prepared which it is thought more accurately reflects the situation on the B&KR and on other HRs. This is detailed in

<table>

</tbody>
</table>
Table 5. For factors that are unaltered from the original system, the scoring remains the same. For new categories scores have been determined based on engineering judgement of their relative significance.

For added clarity, a comparison of the original NR scheme and the new prioritization scheme is shown, without scoring, in
Revised Results

The new HR prioritization scheme was applied to the B&KR. No change was made to the SSHI calculation, for which the results remain as shown in Table 6.
Table 3. These were used with the consequence factors in
Table 5 to calculate revised priorities for monitoring and engineering intervention. The revised priorities are indicated in Figure 4. They now tie in much more effectively with engineering judgement, the high, steep and sometimes wet embankment slopes north of the railway being given the highest priorities. If damaged, these embankments would potentially undermine the line, perhaps in a way not immediately noticeable from the driving cab of an approaching train, and they might result in collapse onto line side property. The resulting disruption would entirely remove the railway’s access to an income stream either from sale of passenger tickets or revenue associated with rail tour movements for which mainline access from Bo’ness Station is required.

**Monitoring and Remediation**

The application of the SSHI calculation and revised prioritization merely calculates a relative risk for given sections of earthwork or rock slope. It does not indicate the presence or absence of an absolute problem; this determination will always rely on on-site inspection by suitably qualified engineers. In the case of the B&KR this has been done, being formally reported in (Watson 2011) and informally on more recent occasions. There have been minor issues connected with the need to repair drainage ditching, and minor slips associated with large trees being uprooted by winter gales, but the underlying stability of all the earth and rock slopes is not currently in question.

However, in the light of the collapses on the SVR and G&WR previously mentioned, and bearing in mind the railway’s responsibility for the safety of its staff, passengers and neighbours, it is appropriate to take steps to manage any potential risk. It is therefore proposed to repeat the risk assessment inspections on a regular basis.

It was notable in both the SVR and G&WR cases that failures were related to drainage issues, where in some cases the existence and operation of culverts was previously unknown (Sowden 2012). A careful investigation of all drainage structures on the B&KR has thus been carried out to ensure that this situation is less likely to arise.

Further, it is commonly noted that earthwork failure is rarely sudden and without warning (for example (Bonnett 2005) section 6.5, p85), and simple monitoring techniques are available to give early warning, the most obvious one being *tell-tales*, which consist of a number of pegs set out in a straight line. Any significant movement of the earthwork would result in pegs moving out of line, which would be readily observable even by an unqualified staff member. The matter could then be further investigated and potential consequences reduced. Four sets of tell-tales have therefore been placed in priority areas 1 to 4 as shown on Figure 4, and will be inspected regularly, with the distance from the running edge of the rail and track cant being monitored at each peg (Figure 5).

**Conclusion and Further Work**

A risk assessment has been carried out on the Bo’ness and Kinneil Railway with the aim of managing potential hazards associated with earthworks and rock slopes supporting a HR. Techniques used by NR to calculate a SSHI and prioritize risk were found to be unsuitable for HR application due to the irrelevance of a number of factors used in determining the severity of potential consequences and the absence of other factors important to HR operations. A revised approach was created taking into account the specific context in which
HRs work, and the revised prioritization gave risk results that related well to engineering judgement regarding the structures in question.

It is concluded that at present the earth and rock slopes on the B&KR are not a cause for concern; however the revised risk management process works well and should be applied regularly, with the highest risk slopes being subject to more frequent formal inspection and recording, with the assistance of simple monitoring techniques to give early warning of any slope movement. This will provide continued reassurance that the B&KR formation remains safe for traffic.

Work on this project is continuing, to provide a more user-friendly method of implementation commensurate with volunteer inspectors in a HR environment, and to trial the method on other HRs, which may lead to further developments in the prioritization scoring, particularly for the new factors introduced as part of this work.

**Acknowledgements**

The authors wish to express their gratitude to Jim Brown, Donald MacKay and NR in Glasgow for their help with the NR SSHI and prioritization systems, to the Scottish Railway Preservation Society, James Robertson, Donald McLeish and Iain Anderson for help in arranging access to the B&KR and to Robert Gardiner, John Edwards, Jim Watson and Huntly Gordon for their assistance with the revision of the risk parameters to suit HRs.

- X indicates the parameter is considered for prioritization.
- The scoring values represent the priority level for each parameter.
