Structure-Preserving Binary Representations for RGB-D Action Recognition

Mengyang Yu, Student Member, IEEE, Li Liu and Ling Shao, Senior Member, IEEE

Abstract—In this paper, we propose a novel binary local representation for RGB-D video data fusion with a structure-preserving projection. Our contribution consists of two aspects. To acquire a general feature for the video data, we convert the problem to describing the gradient fields of RGB and depth information of video sequences. With the local fluxes of the gradient fields, which include the orientation and the magnitude of the neighborhood of each point, a new kind of continuous local descriptor called Local Flux Feature (LFF) is obtained. Then the LFFs from RGB and depth channels are fused into a Hamming space via the Structure Preserving Projection (SPP). Specifically, an orthogonal projection matrix is applied to preserve the pairwise structure with a shape constraint to avoid the collapse of data structure in the projected space. Furthermore, a bipartite graph structure of data is taken into consideration, which is regarded as a higher level connection between samples and classes than the pairwise structure of local features. The extensive experiments show not only the high efficiency of binary codes and the effectiveness of combining LFFs from RGB-D channels via SPP on various action recognition benchmarks of RGB-D data, but also the potential power of LFF for general action recognition.

Index Terms—RGB-D fusion, flux, binary, structure-preserving, dimensionality reduction, local feature

1 INTRODUCTION

RGB-D sensors such as Kinect receive increasing attention in the computer vision community [1]. They have been widely applied to many areas such as: human activity recognition [2], robot path planning [3], object detection [4], scene labeling [5], interactive gaming [6] and 3D mapping [7]. The combination of RGB and depth information enables enhanced capabilities of computer vision algorithms. It also provides an alternative way to learn features from video data for action recognition, especially through learning fused RGB-D representations.

To gain a more robust and accurate representation of samples, local feature descriptors such as: SIFT [8], HOG3D [9], HOG [10], HOF [11] and MBH [12] have been proposed and achieved notable success in classification and recognition. Based on these local features, the Bag-of-Words (BoW) model [13] and the Sparse Coding (SC) algorithm [14] have shown their effectiveness for both image classification and action recognition. During the last decade, extensive efforts have been put on the improvement of BoW and SC. However, in most situations, there are millions of local features with hundreds or even thousands of dimensions in vision-based tasks, which poses a severe restriction on the computational efficiency of similarity search in recognition algorithms. It is, therefore, highly desirable to find a compact and efficient but discriminative representation for local features.

The fast bitwise operations in Hamming space motivate us to propose a local binary representation for RGB-D video data. In this way, the similarity search is simply computing Hamming distances which are conducted by the XOR operation rather than computing Euclidean distances by the addition and multiplication in real numbers. Then the efficiency of classification and recognition algorithms will be significantly improved. Our proposed scheme is two-fold.

First, towards constructing a common representation applicable for both RGB and depth data, we view a video sequence in either RGB or depth as a scalar field in \( \mathbb{R}^3 \) with the frame coordinate \((x, y)\) and the temporal axis \( t \) (for RGB data, we can use the three channels of red, green and blue to form three scalar fields in \( \mathbb{R}^3 \) separately. In the experiments, to alleviate the computational complexity, we only use the grayscale information). To describe this scalar field, we compute the local flux of its gradient field and obtain a feature vector called Local Flux Feature (LFF) for each pixel. Generally speaking, the local flux \( f_r(P) \) at point \( P \) is defined as the rate of the gradient field (flow) passing through a sphere surface with radius \( r \) centered at \( P \). In other words, the local flux at point \( P \) captures the information of the orientation and the magnitude of the gradient field over a neighborhood of \( P \), and \( f_r(P) \), as a continuous function, represents an average quantity of the flow over this neighborhood. Many gradient-based features have been successfully applied to practical situations, since the gradient field represents the direction of the greatest change of a function. Theoretically, the Helmholtz theorem [15] in fluid mechanics states that we only...
need to know the divergence and curl of a twice continuously differentiable vector field to determine it. Given a $C^2$-smooth function $V(x, y, t) : \mathbb{R}^3 \to \mathbb{R}$, its gradient $\nabla V$ satisfies

$$\nabla \times \nabla V = (\nabla_{tx} V - \nabla_{yt} V, \nabla_{xt} V - \nabla_{tx} V, \nabla_{yx} V - \nabla_{xy} V) = 0,$$

which means $\text{curl}(\nabla V) = 0$, showing that the divergence of $\nabla V$ provides the vital information for the gradient field. Fortunately, the divergence theorem converts computing the flux $f_r(P)$ through a closed sphere to computing the volume integral of the divergence inside the sphere. Obviously, computing $f_r(P)$ for every pixel is time-consuming and unnecessary. Thus we only calculate the local fluxes for the regions around the interest points or the points selected by dense sampling in RGB data and the corresponding pixels in depth data.

Second, we fuse the LFFs from RGB and depth channels of points into Hamming space. To make the above features more discriminative and meaningful in Hamming space, we propose a Structure Preserving Projection (SPP) method. Generally speaking, SPP preserves two levels of data structure. In terms of low-level features, we consider the relationship among local feature descriptors, i.e., their pairwise structure, which is maintained in the binary representation learning to embed high dimensional feature descriptors into a lower-dimensional structure-preserved Hamming space. In the learning phase, each pair of local features is given a weak label related to their Euclidean distance. Specifically, a positive pair is a pair of local features, if one feature of the pair is within the $k$ nearest neighbors of the other; otherwise, it is a negative pair.

Considering the shape of the data distribution, the pairwise structure also includes the angles between each pair of local feature descriptors. Taking two negative pairs $(x_1, x_2)$ and $(x_1, x_3)$ as an example (since the majority of pairs are negative), they are encoded to the pairs which have large distances in the Hamming space. Nevertheless, an over-fitting condition is that the pair $(x_2, x_3)$ is possibly mapped to the pair with a small distance as shown in Fig. 1. Therefore, preserving the angles can be regarded as a shape constraint for the structure of pairwise Euclidean distances. It ensures that the shape of data in the original space would not collapse in the Hamming space while pairwise distances are preserved.

Furthermore, in respect of high-level connection, we also want to establish links between samples and classes. The bipartite graph (a.k.a. bigraph) consisting of samples and classes, shows the relationship between samples and classes. To quantize the edges, we use the image-to-class (I2C) distance, which was first introduced in the naive Bayes nearest neighbor (NBN-}

![Fig. 1. Basic principle of the projection with angle-preserving in a two-dimensional example. The distances of two negative pairs $||x_1 - x_2||$ and $||x_1 - x_3||$ are expected to be maximized after the projection. The shape of $(x_1, x_2, x_3)$ has collapsed in the Hamming space without angle-preserving, therefore, lost the discriminative ability.](image-url)
the complementary nature of RGB and depth information.

- Our representation is linear and binary. This makes it extremely fast and useful for many practical applications.

2 Related Work

Feature extraction from RGB video data has been well explored [17], [18], [19], [20]. Detectors such as Spatio-Temporal Interest Points (STIP) [21] and Dollar’s [22] are usually used to locate interest points before feature extraction. Many video descriptors are extended from their counterparts in the image domain [8], [9], [23], [12], [24]. As 3D versions of SURF [25], SIFT [8] and HOF [11], 3D speeded up robust features (SURF3D) [26], 3D scale invariant feature transforms (3D-SIFT) [27] and 3D motion features [28], [29] have been proposed for action recognition respectively. The Histogram of Oriented Gradients (HOG) is widely used in the above schemes, which discretizes the gradient orientations. In our work, however, discretization only performs in the pixel computation. Fathi et al. [30] developed a method to extract mid-level motion features by using the low-level optical flow for action recognition. Recently, the dense trajectories [31] gained high accuracies in most action recognition datasets. However, this method suffers from extremely high computational complexity. More feature extraction methods for action recognition could be found in a survey provided by Poppe [32].

Compared to the conventional RGB cameras, the depth cameras are relatively new. The existing features are specifically extracted for the depth information, since characteristics such as color and texture on depth data are far less than on the RGB data. Motion History Image (MHI) [33] is a typical template matching method for the analysis of depth information and the applications of human motion recognition [34]. Using the depth information only, Shotton et al. [35] gained high accuracies in most action recognition datasets. However, this method suffers from extremely high computational complexity. More feature extraction methods for action recognition could be found in a survey provided by Poppe [32].

Preserving the intrinsic manifold/subspace structure is also involved in our algorithm to seek a more discriminative representation of local features. Manifold learning methods such as ISOMAP [46], Laplacian Eigenmap (LE) [47] and Locally Linear Embedding (LLE) [48], were designed to preserve the manifold structure of data in the original space. A unified review and other manifold learning algorithms can be seen in [49]. Normally, linear methods possess high efficiency. Locality Preserving Projection (LPP) [50] is the first linear projection preserving algorithm that preserves the high-dimensional local structure. Neighborhood Preserving Embedding (NPE) [51] also tries to preserve the local representation of data. Capturing the intrinsic geometrical structure of data, Sparse Concept Coding (SCC) [52], which is a matrix factorization method, provides a sparse representation of the image space. For pairwise structure preserving, a related work for fast vision applications [53] represents each image using a binary vector calculated via boosted coding. In contrast, few works have attempted angle preserving in dimensionality reduction. Caseiro et al. [54] applied rolling map to the classification problem. Although the angles measured by geodesics in the original manifold are equal to the ones in the mapped manifold, the algorithm is not linear.

However, these works mainly focused on the global representations rather than preserving both pairwise
Interest points detection over a video sequence (or dense sampling)

Computing the local flux (with radius 1) of the gradient field for each pixel in the cuboid

Local flux feature

Fig. 2. Illustration of the computation of local fluxes in the gradient field. The output LFF is regarded as a foundation for learning binary codes.

structure of local feature descriptors and bipartite graph structure between samples and classes in the original space for designing efficient binary codes in Hamming space.

In the aspect of hash/binary code learning [55], one classical method is Locality-Sensitive Hashing (LSH) [56]. Another popular technique called Spectral Hashing (SpH) [57] was also proposed to preserve the locality information of data. Recently, a supervised method called Kernel-Based Supervised Hashing (KSH) [58] has shown good discriminative ability of binary codes and outperformed other supervised methods such as Linear Discriminant Analysis Hashing (LDAH) [59], Binary Reconstructive Embeddings (BRE) [60] and Minimal Loss Hashing (MLH) [61]. The above works mainly focus on preserving the pairwise distance, which is one part of SPP. To avoid overfitting as shown in Fig. 1, SPP also takes the pairwise angle into account. Towards local descriptors, Hamming Embedding (HE) [62] was proposed to map real-valued local features to binary codes. SPP contains a sample-to-class relationship [63] when each sample is represented by a set of local descriptors, since most visual tasks are sample-oriented. Experimental results show that these three terms, i.e., the pairwise distance, the pairwise angle and the sample-to-class relationship, all contribute to the outstanding performance of the proposed method.

3 LOCAL FLUX FEATURE

Local features extracted from local regions in an image or a video sequence are used to describe the local structure of a sample. Usually, local regions are the neighborhoods of points which are determined by using an interest point detector or by dense sampling of the image plane or video volume. And then, a feature vector is computed for each local region by characterizing its properties. In our algorithm, we compute the new Local Flux Features (LFFs) from the RGB-D video data and then combine the local feature $x_{Depth}$ from depth information to obtain a concatenated feature vector $X \in \mathbb{R}^D$.

3.1 Flux Computation

The concept of flux has been studied deeply in applied physics, especially in fluid mechanics and electromagnetic theory. The flux of a vector field over a simply-connected closed district (a sphere in this paper) is defined as the quantity of this vector field passing through the district. This quantity includes the information of the orientation and the magnitude of the vector field over the district. It is used for a description of the vector field. To describe a video sequence which is regarded as a scalar field, we consider its gradient field and compute the local flux of the gradient field.

Given a video sequence $V(x,y,t)$ in either RGB$^1$ or depth, it can be seen as a function $V : \mathbb{R}^3 \rightarrow \mathbb{R}$. We assume $V$ is a $C^2$-smooth function, i.e., $V \in C^2(\Omega)$, where $\Omega$ is the district of the video sequence, usually an $L \times W \times H$ cuboid. In fact, in discrete condition, derivative computation can be regarded as an approximation by a convolution operation of matrices. Then for scalar field $V(x,y,t)$, we consider its gradient field $\nabla V(x,y,t) = (\nabla_x V, \nabla_y V, \nabla_t V)$. To describe the gradient field $\nabla V$, we assign an $l \times w \times h$ cuboid centered at each candidate point (interest points or dense samples) and compute the local flux of every pixel (or lattice point if we regard the coordinates of a pixel as integers) in the cuboid. To be specific, denote $B_P(r) = \{(x',y',t')|(x'-x)^2 + (y'-y)^2 + (t'-t)^2 \leq r^2\}$ as the sphere with the center $P = (x,y,t)$ and radius $r$, the local flux at the point $P$ over the sphere $\partial B_P(r)$ is calculated as

$$f_\nu(P) = \int_{\partial B_P(r)} \nabla V \cdot dS,$$

where $dS$ represents the directed area unit of the boundary surface $\partial B_P(r)$. However, computing on

1. In fact, we only need the gray-scale information in our algorithm.
the lattice points on the boundary \( \partial B_P(r) \) is difficult and inaccurate. According to the divergence theorem, we have
\[
\oint_{\partial B_P(r)} \nabla V \cdot dS = \int_{B_P(r)} \nabla \cdot V \, dB_P(r),
\]
i.e., we only need to compute for the points inside the sphere \( B_P(r) \). Note that in the light of the Helmholtz theorem [15] in fluid mechanics, we only need to know the divergence and the curl of a twice continuously differentiable vector field to determine it. Hence, the fact that \( \text{curl}(\nabla V) = \nabla \times \nabla V = 0 \) implies that the divergence of \( \nabla V \) provides the vital information, which is captured by the local flux \( f_r(P) \).

For realistic computation, we adopt the numerical approximation for the discrete condition of pixels:
\[
f_r(P) = \int_{B_P(r)} \Delta V \, dB_P(r) \approx \sum_{Q \in B_P(r) \cap \mathbb{Z}^3} \Delta V(Q),
\]
where \( \Delta \) is the Laplace operator. Suppose there are \( D/2 \) pixels in an \( l \times w \times h \) cuboid, then we compute \( D/2 \) local fluxes in a specific order\(^2\) and obtain a LFF vector \( x = (x_1, \ldots, x_{D/2}) \in \mathbb{R}^{D/2} \). Fig. 2 illustrates the outline of the computation of local fluxes. Having computed the LFF \( x_{RGB} \) from the RGB channel and \( x_{Depth} \) in the corresponding point from the depth channel, we concatenate their normalizations and obtain the new feature
\[
X = \begin{bmatrix} x_{RGB} \mid x_{Depth} \end{bmatrix}^T \in \mathbb{R}^D.
\]

The combined LFF is regarded as the basic feature for the later learning of binary codes in our algorithm.

4 Structure Preserving Projection

In this section, we introduce our Structure Preserving Projection (SPP) algorithm. SPP simultaneously preserves the local structure and the integrated shape of local features. In addition, SPP also considers a higher level relationship among local features, i.e., the bipartite graph consisting of samples and classes. SPP aims to seek a specific matrix \( \Theta \in \mathbb{R}^{D \times d} \) \((d < D)\) to construct a binary function
\[
H(X) = \text{sgn}(\Theta^T X),
\]
such that their discriminative ability for action recognition is improved. For computational convenience, we choose \( \{-1, +1\} \) rather than \( \{0, 1\} \) to represent binary codes in our algorithm.

\(^2\)In the experiments, we obtain the LFF by listing the corresponding local flux values in the following pixel order: \((1, 1, 1), \ldots, (l, 1, 1), (1, 2, 1), \ldots, (l, 2, 1), \ldots, (l, w, 1), \ldots, (l, w, h)\). In fact, the order has no effect on the final recognition results. The only requirement is the consistency of order in a vision task.

4.1 Pairwise Structure Preserving

We denote the set composed of all local features by \( \mathcal{F} = \{X_1, \ldots, X_N\} \), where \( N \) is the number of local features in training data. As mentioned above, we aim to seek the binary representations with discriminative ability in the lower-dimensional space. We are concerned about the relationship between every two local features in the high-dimensional space, which should also be retained in the lower-dimensional space.

4.1.1 Pairwise Label

First, we assign a weak label for each pair of local features. With the pairwise labels, acquiring the class information of each local feature is unnecessary. Besides, similar local features with small Euclidean distances may appear in samples from many different classes. Motivated by the binary property of \( H(X) \), we employ the pairwise label \( \{-1, +1\} \) to represent the relationship between two local features based on the pairwise distance between them. Thus we have the pairwise label
\[
\ell_{ij} = \begin{cases} +1, & X_i \in N_k(X_j) \text{ or } X_j \in N_k(X_i), \\ -1, & \text{otherwise}\end{cases}
\]
where \( N_k(X) \) is the set of \( k \) nearest neighbors of \( X \). To maintain the local structure, we make the product of each component in \( H(X_i) \) and \( H(X_j) \) consistent with their pairwise label \( \ell_{ij} \), i.e., \( H(X_i)_m \cdot H(X_j)_m = \ell_{ij}, \forall m \). We denote \( P = \{(i,j) | X_i, X_j \in \mathcal{F}\} \). Therefore, we need to minimize the following function
\[
\sum_{(i,j) \in P} \sum_{m=1}^{D} (\ell_{ij} - H(X_i)_m H(X_j)_m)^2
\]
\[
= \sum_{(i,j) \in P} \sum_{m=1}^{D} (2 - 2\ell_{ij} H(X_i)_m H(X_j)_m)
\]
\[
= \sum_{(i,j) \in P} \left(2D - 2\ell_{ij} \sum_{m=1}^{D} H(X_i)_m H(X_j)_m\right)
\]
\[
= \sum_{(i,j) \in P} 2D - 2\ell_{ij} \langle H(X_i), H(X_j) \rangle.
\]

Then equivalently, we only need to maximize
\[
\sum_{(i,j) \in P} \ell_{ij} \langle H(X_i), H(X_j) \rangle.
\]

The above function reaches its maximum value when \( \ell_{ij} \text{sgn}(\Theta^T X_i) \) and \( \text{sgn}(\Theta^T X_j) \) are similarly sorted due to the rearrangement inequality [64]. In other words, if \( \ell_{ij} = 1 \), \( X_i \) and \( X_j \) are then similarly encoded and vice versa.

Considering the effect of noise, we additionally assign a pairwise weight \( W^P_{ij} \) to the local feature pair \((i,j)\) to avoid the disturbance:
\[
W^P_{ij} = \exp \left(-l_{ij} \|X_i - X_j\|^2\right).
\]
Then the objective function for pairwise labels becomes
\[
\sum_{(i,j) \in P} W_{ij} \ell_{ij}(H(X_i), H(X_j)). \tag{9}
\]

4.1.2 Pairwise Angle

In addition to the distance factor, we are also concerned about the shape of the entire set of local features, which is regarded as a constraint for preserving the pairwise Euclidean distances. The shape constraint firms the data structure in the projected space and avoids some certain errors caused by the pairwise labels. We denote the angle between two local features \(X_i\) and \(X_j\) by \(\theta_{ij}\). Note that angle \(\theta_{ij}\) is with the vertex at coordinate origin. Thus, the local features should be centralized before the further learning process. Orthogonal transformation \((d = D\) and \(\Theta^T \Theta = \Theta \Theta^T = I)\) preserves the lengths of local features and the angles between them since we have \(\langle \Theta^T X_i, \Theta^T X_j \rangle = X_i^T \Theta \Theta^T X_j = X_i^T X_j = \langle X_i, X_j \rangle\), \(\forall i, j\). When \(d < D\), however, this property does not hold in orthogonal projection. We hope the angle \(\hat{\theta}_{ij}\) in the projected space\(^3\) is (approximately) equal to \(\theta_{ij}\). Note that the distances are irrelevant with the angles, i.e., the pair of local features with a long distance may have a large angle. Thus it is desirable to retain the angles of all pairs. We define our optimization problem for angle preserving in the low dimensional space:

\[
\arg \max_{\Theta} \sum_{(i,j) \in P} \langle X_i, X_j \rangle \cdot \langle \Theta^T X_i, \Theta^T X_j \rangle. \tag{10}
\]

Although it is the optimization for preserving the inner product, the following proposition shows that the optimal \(\Theta^*\) preserves the pairwise angles.

Proposition 1: Suppose \(\Theta^*\) is the optimal solution of the optimization problem (10), then for any \(1 \leq i, j \leq N\), the projection \(\Theta^*\) preserves the angle between the local features \(X_i\) and \(X_j\).

Proof: According to the Cauchy-Schwarz inequality, we have
\[
\sum_{(i,j) \in P} \langle X_i, X_j \rangle \cdot \langle \Theta^T X_i, \Theta^T X_j \rangle \leq \left( \sum_{(i,j) \in P} \langle X_i, X_j \rangle^2 \right)^{\frac{1}{2}} \left( \sum_{(i,j) \in P} \langle \Theta^T X_i, \Theta^T X_j \rangle^2 \right)^{\frac{1}{2}},
\]
and the equality holds if and only if \(\langle X_i, X_j \rangle \) \((i,j) \in P\) and \(\langle \Theta^T X_i, \Theta^T X_j \rangle \) \((i,j) \in P\) are collinear. We can first set a norm constraint \(\sum_{(i,j) \in P} \langle \Theta^T X_i, \Theta^T X_j \rangle^2 = 1\) for \(\Theta\). Then the objective function in Eq. (10) is smaller than a constant. If \(\Theta^*\) is the optimal solution of the optimization problem (10), the left-hand-side of the above inequality reaches its maximum value at \(\Theta^*\). Then there exists a constant \(\lambda \in \mathbb{R}\) such that
\[
\frac{\langle (\Theta^*)^T X_i, (\Theta^*)^T X_j \rangle}{\langle X_i, X_j \rangle} = \lambda, \ \forall (i,j) \in P.
\]

Since for \(i = j\), we have \(\| (\Theta^*)^T X_i \| = \lambda \| X_i \|\), then \(\lambda > 0\). Therefore, for the projected angle \(\hat{\theta}_{ij}\) it satisfies
\[
\cos \hat{\theta}_{ij} = \frac{\langle (\Theta^*)^T X_i, (\Theta^*)^T X_j \rangle}{\| (\Theta^*)^T X_i \| \| (\Theta^*)^T X_j \|} = \frac{\langle (\Theta^*)^T X_i, (\Theta^*)^T X_j \rangle}{\sqrt{\langle (\Theta^*)^T X_i, (\Theta^*)^T X_i \rangle} \sqrt{\langle (\Theta^*)^T X_j, (\Theta^*)^T X_j \rangle}} = \frac{\lambda(X_i, X_j)}{\sqrt{\lambda(X_i, X_i)} \sqrt{\lambda(X_j, X_j)}} = \frac{\langle X_i, X_j \rangle}{\|X_i\| \|X_j\|} = \cos \theta_{ij},
\]
which implies that the projection matrix \(\Theta^*\) is an angle-preserving projection.

4.2 Bigraph Regularization

Not only the pairwise structure of local features, but also the connection between samples and classes, which is regarded as a higher level relationship among local features, is considered in our algorithm. We use the image-to-class (I2C) distance to measure the bipartite graph (a.k.a. bigraph) that consists of video samples and classes. Although the I2C distance was first introduced to measure the distances between images and classes, it can also be applied to all kinds of samples that are represented by local features. Our goal is to preserve the I2C distances in the lower dimensional space. Given the set of local features of a sample \(X_i = \{X_{i1}, \ldots, X_{im}\}\), which contains all local features of sample \(i\), the distance between sample \(i\) and class \(c\) is defined as
\[
I_c^i = \sum_{X \in X_i} \| X - \text{NN}_c^c(X) \|^2, \tag{11}
\]
where \(\text{NN}_c^c(X)\) is the nearest neighbor (NN) of the local feature \(X\) in class \(c\) and \(\| \cdot \|\) is the \(L_2\)-norm.

However, the complexity of NN-search linearly depends on the number of local features, which renders the nearest neighbor search in such a large-scale space of local features of each class will still cost much time. Hence, we first implement a K-means clustering algorithm for each class. In other words, we first find \(K\) centroids for each set \(\bigcup_{c=1}^{C} \bigcup_{X_i \in C} X_i\), where \(C\) is the number of classes and \(C(\cdot) \in \{1, \ldots, C\}\) is the label information function that represents the class label of the input. In this way, the searching range of nearest neighbors is reduced to the set of cluster centers, which has a much smaller size than the original space, i.e., for \(c = 1, \ldots, C\), we set
\[
\text{NN}_c^c(X) \in \text{Centroids } \{S_1, \ldots, S_K\} \text{ of } \bigcup_{C(X_i)=c} X_i.
\]
Having obtained I2C distances, we build a bigraph $G = (V_1, V_2, E)$, where $V_1$ and $V_2$ are the node sets of samples and classes respectively. $G$ is a complete and weighted bigraph. For each edge in $E$ connecting sample $i$ and class $c$, it has the weight $W^D_{ic}$ determined by the I2C distance, named the I2C similarity. By heat kernel, we define the I2C similarity as follows:

$$W^H_{ic} = \exp \left(-\left(I^c_i \right)^2 / \sigma \right), \quad i = 1, \ldots, n, \quad c = 1, \ldots, C,$$

where $\sigma$ is the Gaussian smoothing parameter and $n$ is the number of training samples. Correspondingly, we have the I2C distance in the objective Hamming space:

$$\hat{I}^c_{X_i} = \sum_{X \in X_i} \|H(X) - \text{NN}^c(H(X))\|^2. \quad (13)$$

With the above defined I2C similarity $W^H_{ic}$ and the projected I2C distance $\hat{I}^c_{X_i}$, we can define the following optimization problem to quantize the bigraph regularization, i.e., I2C structure in the low dimensional space:

$$\arg \min_{\Theta} \sum_{i=1}^n \sum_{c=1}^C \hat{I}^c_{X_i} \cdot W^H_{ic}. \quad (14)$$

By minimizing the above equation, the sample which has a small I2C distance to class $c$ in the high dimensional space is still close to class $c$ in the low dimensional space. According to the rearrangement inequality [64], the above objective function reaches its minimum value if and only if $\{\hat{I}^c_{X_i}\}$ and $\{I^c_{X_i}\}$ are similarly sorted, which means the projected I2C distances preserve the bigraph structure in the high dimensional space.

### 4.3 Objective Function and Optimization

In addition, to make the projected space more compact, we set the orthogonality constraint on the projection matrix, i.e., $\Theta^T \Theta = I$. Combining the objective functions for the pairwise structure and the bigraph regularizer, we obtain our final optimization problem for SPP:

$$\arg \max_{\Theta^T \Theta = I} \sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \langle H(X_i), H(X_j) \rangle + \sum_{(i,j) \in P} \langle X_i, X_j \rangle \cdot (\Theta^T X_i, \Theta^T X_j)$$

$$- \beta \sum_{i=1}^n \sum_{c=1}^C \hat{I}^c_{X_i} \cdot W^H_{ic}, \quad (15)$$

where $\beta$ is the regularization parameter.

**Optimization:** Considering the discreteness of the binary function, we first use approximation $\text{sgn}(x) \approx x$ to relax the objective function in the optimization problem (15) into a real-valued space. Then the objective function of the pairwise label part (see Eq. (9)) becomes

$$\sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \langle H(X_i), H(X_j) \rangle = \sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \langle \text{sgn}(\Theta^T X_i), \text{sgn}(\Theta^T X_j) \rangle$$

$$\approx \sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \langle \Theta^T X_i, \Theta^T X_j \rangle$$

$$= \sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \text{tr}(\Theta^T X_i (\Theta^T X_j)^T)$$

$$= \sum_{(i,j) \in P} W^{P}_{ij} \ell_{ij} \text{tr}(\Theta^T X_i X_j^T \Theta).$$

And for I2C distances, we denote $\text{NN}^c(X) = X^c$. Note that after applying projection matrix $\Theta$, the nearest neighbors may change. However, for the large-scale local feature space, we approximately adopt the sum of the distances from $\Theta^T X$ to the projected nearest neighbor $\Theta^T X^c$. Then the projected I2C distance (see Eq. (13)) after applying matrix $\Theta$ becomes

$$\hat{I}^c_{X_i} \approx \sum_{X \in X_i} \|\Theta^T X - \Theta^T X^c\|^2$$

$$= \sum_{X \in X_i} \|\Theta^T (X - X^c)\|^2$$

$$= \sum_{k=1}^{m_i} \text{tr}(\Theta^T (X_{ik} - X^c_{ik})(\Theta^T (X_{ik} - X^c_{ik})^T))$$

$$= \sum_{k=1}^{m_i} \text{tr}(\Theta^T (X_{ik} - X^c_{ik})(X_{ik} - X^c_{ik})^T \Theta)$$

$$= \sum_{k=1}^{m_i} \text{tr}(\Theta^T \Delta X_{ik}^c (\Delta X_{ik}^c)^T \Theta),$$

where $\Delta X_{ik} = X_{ik} - X^c_{ik}, k = 1, \ldots, m_i$. Thus, by simple algebraic derivation, the optimization problem (15) is reduced to

$$\arg \max_{\Theta^T \Theta = I} \text{tr}(\Theta^T M \Theta), \quad (16)$$

where

$$M = \sum_{(i,j) \in P} (W^{P}_{ij} \ell_{ij} + \langle X_i, X_j \rangle X_i X_j^T$$

$$- \beta \sum_{i=1}^n \sum_{c=1}^C \sum_{j=1}^{m_i} W^H_{ic} \Delta X_{ij} \Delta X_{ij}^T. \quad (17)$$

Notice that $W^{P}_{ij} \ell_{ij} + \langle X_i, X_j \rangle = W^{P}_{ij} \ell_{ji} + \langle X_j, X_i \rangle, \forall i, j$, then we have

$$M = \sum_{1 \leq i < j \leq N} (W^{P}_{ij} \ell_{ij} + \langle X_i, X_j \rangle)(X_i X_j^T + X_j X_i^T)$$

$$+ \sum_{i=1}^N (W^{P}_{ii} \ell_{ii} + \langle X_i, X_i \rangle)X_i X_i^T$$

$$- \beta \sum_{i=1}^n \sum_{c=1}^C \sum_{j=1}^{m_i} W^H_{ic} \Delta X_{ij} \Delta X_{ij}^T.$$
Thus $M$ is a real-valued symmetric matrix. It is clear that the solution to the optimization problem (16) is the eigenvectors corresponding to the largest $d$ eigenvalues of $M$. We summarize our algorithm in the following Algorithm 1.

**Algorithm 1 Structure Preserving Projection for Local Flux Feature**

**Input:** Training video sequences $V_1, \ldots, V_n$ in gray-scale and $V'_1, \ldots, V'_n$ in depth, the radius $r$ for the sphere $B_p(r)$, the parameter $k$ for pairwise structure preserving, the number of centroids $k$ in K-means, the label information function $C(\cdot) \in \{1, \ldots, C\}$, the regularization parameter $\beta$ and the objective dimension $d$.

**Output:** The projection matrix $\Theta$.

1. Detect interest points (or densely sample) $\{P_{1}, \ldots, P_{m}\}$ from the $i$-th training video $V_i$, $i = 1, \ldots, n$;
2. Compute two LFFs for each point in gray-scale and depth respectively by Eq. (3) and combine them by Eq. (4) to obtain the local feature set of the $i$-th training video $X_i = \{X_{1i}, \ldots, X_{ni}\}$ and the whole local feature set $F = \bigcup X_i = \{X_1, \ldots, X_N\}$;
3. Centralize $X_i \rightarrow \sum_{j=1}^{N} X_j, \forall i$;
4. Construct local feature pairing set $P = \{(i, j)|X_i, X_j \in F\}$ and their corresponding pairwise labels $\ell_{ij} = \{+1, -1\}$, where $\ell_{ij} = +1$ if $X_i \in N_k(X_j)$ or $X_j \in N_k(X_i)$ and $\ell_{ij} = -1$ otherwise;
5. Employ the K-means clustering algorithm on the set of local features of each class $\bigcup_{C(X_i)=c} X_i, c = 1, \ldots, C$;
6. Compute pairwise weight $W_{ij}^{cf}$ and I2C similarity $W_{ic}^{cf}$ by Eqs. (8) and (12);
7. Compute the matrix $M$ by Eq. (17);
8. return the eigenvectors corresponding to the largest $d$ eigenvalues of $M$.

**4.4 Complexity Analysis**

In this section, we provide a time complexity analysis of our algorithm. During the training phase, our algorithm mainly consists of three parts. The first part is the computation of LFFs. The derivative computation is actually the convolution of matrices which at most needs $O(3DL_m \log L_m)$ time [65], where $L_m = \max\{L, W, H\}$. The second part is the computation of pairwise structure preserving. The k-NN algorithm in the construction of pairwise labels and the computation of pairwise angles cost $O(kN^2)$ and $O(N^2)$ time respectively. The last part is the construction of the I2C similarity matrix ($W_{ic}^{cf}$). The time complexity of this part is $O(nCKDN)$. In total, the time complexity of the training phase is at most $O(3DL_m \log L_m) + O((k + 1)N^2) + O(nCKDN)$.

In the test phase, binary codes can significantly reduce the runtime of the recognition algorithm since the distance computation in Hamming space is simply based on the XOR operation. Denote $\tau_m$ and $\tau_{XOR}$ as the time of one multiplication and one XOR operation respectively. Then the computational complexity of NBNN in the original space is $O(N_{\text{train}}, N_{\text{test}}D)\tau_m$, where $N_{\text{train}}$ and $N_{\text{test}}$ are the numbers of local features in training and test sets respectively. With the binary local features, the time complexity is reduced to $O(N_{\text{train}}, N_{\text{test}}d)\tau_{XOR}$. In general, we have $d \ll D$ and $\tau_{XOR} \ll \tau_m$. Thereby, when $N_{\text{train}}$ and $N_{\text{test}}$ are in the magnitude of millions or even greater, the hashing algorithm’s effect is self-evident. We will list the run-time in the following section.

**5 Experiments and Results**

In this section, we systematically evaluate our proposed method on three different RGB-D benchmarks: the SKIG hand gesture dataset [66], the MSR Daily Activity3D dataset [2] and the CAD-60 activity dataset [67]. Fig. 3 shows some example frames of these three datasets. Details of the datasets are introduced in the following subsection.

**5.1 Datasets and Settings**

The SKIG dataset has 2160 hand gesture sequences (1080 RGB sequences and 1080 depth sequences) collected from 6 subjects. All these sequences are synchronously captured with a Kinect sensor (including a RGB camera and a depth camera). This dataset collects 10 categories of hand gestures in total: circle (clockwise), triangle (anti-clockwise), up-down, right-left, wave, “Z”, cross, comehere, turnarround and pat. In the collection process, all these ten categories are performed with three hand postures: fist, index and flat. To increase the diversity, the sequences are recorded under 3 different backgrounds (i.e., wooden board, white plain paper and paper with characters) and 2 illumination conditions (i.e., strong light and poor light). Consequently, for each subject, there are $10(\text{categories}) \times 3(\text{poses}) \times 3(\text{backgrounds}) \times 2(\text{illumination}) \times 2(\text{RGB and depth}) = 360$ gesture sequences. The training size for each category is varied as one of $\{10, 20, 35, 45, 60, 70\}$ and the rest of the sequences are used for testing.

The MSR Daily Activity3D dataset is a human activity dataset captured with the RGB channel and the depth channel using the Kinect sensor. The total sequence number is 640 (i.e., 320 sequences for each channel) with 16 activities: drink, eat, read book, call cellphone, write on a paper, use laptop, use vacuum cleaner, cheer up, sit still, toss paper, play game, lie down on sofa, walk, play guitar, stand up, sit down. There are 10 subjects in the dataset and each subject performs each activity twice, once in standing position, and once in sitting position. The training size for each subject is chosen as one of $\{5, 10, 15, 20, 25\}$ and the rest is used for testing.

The Cornell Activity dataset (CAD-60) contains 60 RGB-depth sequences acted by four subjects and captured with a Kinect camera. The actions in this dataset are categorized into five different environments: office, kitchen, bedroom, bathroom, and living room. Three or four common activities were identified for each environment, giving a total of twelve unique

This work is licensed under a Creative Commons Attribution 3.0 License. For more information, see http://creativecommons.org/licenses/by/3.0/.
actions: rinsing mouth, brushing teeth, wearing contact lens, drinking water, opening pill container, cooking (chopping), cooking (stirring), talking on couch, relaxing on couch, talking on the phone, writing on whiteboard, working on computer. The training size for each action is assigned as one of \{1, 2, 3, 4\} and remaining sequences are adopted for testing.

All the training samples are selected randomly from every class in each dataset and all the procedures are repeated five times. We report the averages as the final results.

For the experimental settings, we fix the size of the cuboid \(l \times w \times h\) in the computation of LFF as \(7 \times 7 \times 9\). We set \(r = 4, 4, 5\) in each dataset respectively due to the comparison results with different radii \(r\) in Table 1. If the radius \(r\) is too small, the LFF degenerates to the second order derivative, and if \(r\) is too big, LFFs are almost the same for adjacent pixels, which tends to be less discriminative. We always set \(k = 15\) for the pairwise data structure. Actually, we utilize the training data as the cross-validation set in SPP. The parameter \(K\) of the K-means is selected from one of \{100, 200, \ldots, 1000\} with the step of 100, which yields the best performance by 10-fold cross-validation. The optimal parameter \(\beta\) is selected from \{0.1, 0.2, \ldots, 1.0\} with the step of 0.1 by 10-fold cross-validation on the cross-validation set, as well. In particular, the nested cross-validation strategy is applied to these two parameters, i.e., \(K\) and \(\beta\). We always first fix the value of \(K\) as one of \{100, 200, \ldots, 1000\} and

select the best parameter $\beta$ from $\{0.1, 0.2, \ldots, 1.0\}$, and then assign another value to $K$ and select the best parameter $\beta$ from $\{0.1, 0.2, \ldots, 1.0\}$ again. In this way, the optimal pair of parameters $K$ and $\beta$ can be obtained under the nested cross-validation strategy.

Since the acceleration of NBNN is quite conspicuous using the Hamming distance instead of the $L_2$-norm in the NN-search and NBNN classifier always outperforms the BoW model, we mainly use NBNN to evaluate our recognition precision.

### 5.2 Compared Results

First of all, we illustrate the effectiveness of all the three terms used in SPP, i.e., the pairwise label preserving term, the pairwise angle preserving term and the bigraph regularization. We remove one of them and keep the other two terms, and optimize the problem in (15). The results are listed in Table 2, from which we can observe that the bigraph regularization contributes the most to the accuracies.

Next, for all three datasets, we apply three different schemes to achieve RGB-D video classification: (1) Detected interest points$^4$ + LFF + SPP; (2) Dense sampling$^5$ + LFF + SPP; (3) Detected interest points + LFF + SPP + Bag-of-Words. For (1) and (2), we adopt NBNN as the classifier and the linear SVM is applied for the third scheme for classification. The codebook lengths of BoW for each dataset are chosen as one of $\{500, 1000, 1500, 2000\}$ and the best results are reported.

For each scheme, we apply SPP on LFFs from RGB and depth information. According to all the possible combinations, we evaluate four different kinds of local binary codes on three datasets: LFF(RGB-D)+SPP denotes our full algorithm; LFF(RGB)+SPP only uses RGB information to compute LFFs and then apply SPP; LFF(D)+SPP only uses depth information to compute LFFs and then apply SPP; LFF+SPP(RGB-D) concatenates LFF(RGB)+SPP and LFF(D)+SPP.

From Figs. 4–6, we can observe that the performance of our full algorithm is consistently higher than that of other versions on the three datasets. And dense sampling generally outperforms interest points detection due to the large amount of local feature descriptors. Another observation is that LFF(RGB-D)+SPP always outperforms LFF+SPP(RGB-D), since the former outputs the fused binary representation with the consideration of the structures of RGB-D features. In contrast, LFF+SPP(RGB-D) outputs binary codes separately for RGB and depth features, therefore, loses the connection between RGB and depth features.

In Fig. 7, we also compare the performance of our algorithm with different code lengths by using different point selection methods, i.e., interest points detection (Dollar’s detector and STIP) and dense sampling, on the three datasets. It is noticeable that, on the CAD-60 dataset, the accuracy of dense sampling is slightly lower than that of interest points detection because the noise of the background has a negative effect on the dense sampling when the code length increases. In this situation, the detection method is more effective than dense sampling.

Finally, Fig. 8 shows the average runtime comparison. Our learned binary codes show a significant advantage compared to the original LFF consisting of real numbers since NBNN largely depends on NN-search. All the experiments are conducted using Matlab 2013a on a server configured with a 12-core processor and 128G of RAM running the Linux OS.

### 5.3 Comparison with Other Methods

In Table 3, we first compare the proposed LFF descriptor with state-of-the-art video descriptors (i.e., HOG, HOF, MBH, HON4D and HOG3D) for RGB-D action recognition. All the methods are computed on the interest points from the RGB channel detected by Dollar’s detector and the corresponding points from the depth channel. As we can see, LFF outperforms HOG, HOF, MBH and HOG3D in the RGB and depth channels and the RGB-D concatenation scheme. Although HON4D, as a descriptor specifically designed for depth sequences, achieves better performance in the depth channel, it can only be extracted from depth data and the recognition accuracies are relatively low. In contrast, our LFF is considered to be a general feature descriptor for both RGB and depth data and LFF in the RGB-D concatenation scheme reaches the highest accuracy in the experiment of feature comparison.

Since SPP is a projection for learning binary codes, we can also compare our SPP algorithm with other

---

5. We set the distance between adjacent pixels as 5.
hashing methods. In our experiments, we compare the proposed method against seven general hashing algorithms including KSH [58], BRE [60], MLH [61], LSH [56], SpH [57], AGH [68], PCAH [69], BSSC [53] and RBM [70]. All the above methods are computed on the same extracted LFFs for a unified standard. All the compared methods are then evaluated on five different lengths of codes (32, 48, 64, 80, 96) and their results at 96-bit, which appear to be the best, are reported. Under the same experimental setting, all the parameters used in the compared methods have been strictly chosen according to their original papers. We list the compared results in Table 3 where RGB channel and depth channel represent only employing the methods in RGB and depth respectively, RGB-D fusion is the procedure of our algorithm and RGBD cat is the concatenation of the features gained in RGB channel and depth channel. The results of the above mentioned other hashing methods in RGB-D fusion are not consistently higher than that in RGB-D concatenation, since not all of them preserve data structure. The training sizes are 70, 25 and 4

The LFF features are extracted along the same trajectories in the video sequences as the dense trajectory features.

for datasets SKIG, MSRDailyActivity3D and CAD-60, respectively. Table 3 also reports the recognition accuracies of LFF and HOG3D using the improved Fisher vector (IFV) [71], for which 200 Gaussians are used in the GMM. The results show two phenomena: 1. LFF as a continuous feature outperforms other discrete histogram based features; 2. SPP outperforms other hashing methods.

5.4 Statistical Significance Test

To show the statistical significance of improvements, we conduct a t-test on the MAP improvements. In testing the null hypothesis that the population mean is equal to a specified value \( \mu_0 \), the statistic

\[
t = \frac{\bar{x} - \mu_0}{s/\sqrt{n}}
\]

is used, where \( \bar{x} \) is the sample mean, \( s \) is the sample standard deviation of the sample and \( n \) is the sample size. Then the degree of freedom used in the test is \( m - 1 \). We set \( m = 10 \) and code length \( d = 96 \) for this experiment. Table 4 lists the one-tail results of the t-test, which shows that the improvements are statistically significant.

5.5 Results on RGB Video dataset

To further illustrate the effectiveness of LFF, in this experiment, we compare the RGB version of LFF with the state-of-the-art feature: dense trajectory features on the UCF YouTube [72] and HMDB51 [73] datasets for action recognition. The UCF YouTube dataset contains 1168 video sequences collected from 11 action categories. Most of them are sports activities, which are drawn from existing YouTube videos; therefore, the dataset contains large variations and approximates a real-world database. For this dataset, we deliberately use the full-sized sequences without any bounding boxes as the input to evaluate our method’s robustness against complex and noisy backgrounds. We use the Leave-One-Out setup, i.e., testing on each original sequence while training on all the other sequences. The HMDB51 dataset contains 6849 realistic action sequences collected from a variety of movies and online videos. Specifically, it has 51 action classes and each has at least 101 positive samples. We adopt the official setting of [73] with three train/test splits. Each split has 70 training and 30 testing clips for each class. Table 5 illustrates that our proposed LFF \((r = 5)\) can achieve competitive results with dense trajectory feature (DTF) which produces the state-of-the-art performance on recent publications [31], [74]. Note that for fair comparison of feature descriptors, all the compared features are extracted around the same points, i.e., the points on the trajectories.

6 Conclusion

The basic goal of this paper is to obtain a fused local binary representation for RGB-D action recognition. To achieve this goal, we first introduced a continuous local descriptor called Local Flux Feature (LFF) based on the gradient field of video data, which is more suitable for the discretization of binary codes than histogram based local descriptors. After acquiring LFFs from RGB and depth channels, we applied the Structure Preserving Projection (SPP) to learn discriminative local binary representations. SPP preserves the characteristics in two levels including pairwise structure of local features and the relationship between video samples and classes at the same time without the collapse of data structure. The systematical experiments have shown not only the high efficiency of the proposed local binary representations, but also its superior performance than other local features and other hashing methods in terms of recognition accuracy on three RGB-D datasets.
