Highlights

- We fabricated a 8.1% efficient Cu$_2$ZnSnSe$_4$ (CZTSe) solar cells with an open circuit voltage of 434 mV.
- Decreasing the Cu content in the CZTSe absorber layer, the unit cell volume decreases.
- Decreasing the Cu content, increases the ordering of Cu and Zn in the kesterite type structure.
Systematic compositional changes and their influence on lattice and optoelectronic properties of Cu2ZnSnSe4 kesterite solar cells

Kesterite thin films solar cells have been studied in recent years as a potential earth abundant alternative to other thin film technologies such as the ones based on the chalcopyrite Cu(In,Ga)Se2 (CIGS). However, the efficiency of the kesterite devices is still low and needs further development. In order to increase the performance of the kesterite solar cells, a better understanding of the influence of variations of compositions on the crystal lattice of the absorber layer is needed. This paper presents a study of how variations in the Cu content in the Cu2ZnSnSe4 (CZTSe) absorber layer affects the crystal structure and therefore changes the optoelectronic properties of the solar cell. Three setsof CZTSe absorbers with different Cu content were synthesised by sputtering of metallic targets followed by a rapid thermal selenisation process. An accurate characterisation of the lattice parameters of the unit cell is presented, showing that a decrease of the Cu content in the CZTSe absorber layer diminishes the unit cell volume. This decrease in volume is related to an increase in the concentration of [V\text{Cu} + Zn\text{Cu}] and the ordering of the Cu/Zn atoms in the (001) plane. The variations in the lattice of CZTSe induced by decreasing the Cu content cause an increase of the bandgap of absorber layer, which leads to an increase of the open circuit voltage (V_{\text{OC}}) in the devices. The best solar cell was based on the absorber layer with the lowest Cu content.
and yielded an efficiency of 8.1% with a fill factor of 59.8%, \( J_{sc} = 31.1 \text{mA/cm}^2 \) and \( V_{oc} = 434 \text{mV} \).

1. Introduction

Thin film solar cells based on \( \text{Cu}_2\text{ZnSn(S,Se)}_4 \) (CZTSSe) have been studied as an alternative to \( \text{Cu(In,Ga)}\text{Se}_2 \) (CIGSe). To date, the highest efficiency achieved has been 12.6% [1]. However, it has been suggested that small area devices need to reach an efficiency of 19% in order to justify commercial manufacture at a significant level [2]. Currently the material presents many barriers that need to be better understood in order to continue increasing the performance of CZTSSe based solar cells. The open circuit voltage (\( V_{oc} \)) deficit, defined as \( E_g/q - V_{oc} \), is substantially larger for CZTSSe devices than for good CIGSe devices which generally present \( V_{oc} \) deficits lower than 500 mV [3]. There are several possible explanations for the \( V_{oc} \) deficit that CZTSSe devices currently present. Firstly, \( \text{Cu}_2\text{ZnSnSe}_4 \) (CZTSe) and \( \text{Cu}_2\text{ZnSnS}_4 \) (CZTS) present a very narrow stoichiometric region [4-6]. In addition, it has been demonstrated that at high temperatures, when in contact with metallic Mo which is normally used for the back contact in kesterite solar cells, CZTSSe decomposes [7, 8]. It has also been proven that high chalcogen partial pressures are required when crystallising the CZTSSe in order to avoid the decomposition of the absorber layer on the surface [9] that leads to a decrease in the photovoltaic performance of the devices. In the bulk of the absorber layer, many questions are still to be resolved regarding the crystal structure of these materials. A better understanding of the formation and impact of defects needs to be developed in order to decrease the current \( V_{oc} \) deficit of the best kesterite devices [10]. A combination of neutron and X-ray diffraction analysis demonstrated that CZTSe and CZTS crystallise in the kesterite type structure and also that \( \text{Cu}_2\text{Zn} \) and \( \text{Zn}_{\text{Cu}} \text{antisites} \) in the (001) planes at \( z = 1/4 \) and \( 3/4 \) are present in high concentration opening the discussion of how ordered are the synthesized kesterite-type compounds [11]. The order-disorder transition has been studied by Scragget al. for CZTSe [12], Kraemmer et al. for CZTSSe [13], and Redinger et al. and Reyet al. for CZTSe [14]. It has been concluded that this transition can change the effective bandgap of the material by more than 100 meV, thus affecting the Voc of solar cells synthesized from the same absorbers with different degrees of ordering [15].

It has been reported several times in the literature that Cu-poor and Zn-rich compositions are needed to make high efficiency solar cells, although more experimental data regarding composition is needed in order to determine how the variation in the metal ratios affects the crystal structure of CZTSSe compounds in thin films and the correlation with the optoelectronic properties of the solar cells processed from them. When different publications where solar cells and their compositions are reported are compared, it is difficult to identify trends and therefore difficult to conclude why the devices work better within certain values of composition. If we also add errors in the compositional
measurements, different calibration methods, and different techniques used for measuring, it is even more difficult to define certain values of compositions and relate them to the properties of the solar cells.

First principle calculations have explained theoretically why Cu-poor, Zn-rich kesterite solar cells should be of higher efficiency [16]. It was concluded that \( V_{\text{Cu}} \) could contribute to p-type conductivity. It was also shown that some self-compensated defect clusters \([V_{\text{Cu}} + Zn_{\text{Cu}}]\), \([Zn_{\text{Sn}} + 2Zn_{\text{Cu}}]\) and \([2Cu_{\text{Zn}} + Sn_{\text{Cu}}]\) have low formation energy and can be present in high population either in CZT and in CZTSe. \([2Cu_{\text{Zn}} + Sn_{\text{Zn}}]\) could induce electron-trapping effects and \([V_{\text{Cu}} + Zn_{\text{Cu}}]\) could induce a downshift in the valence band that might be beneficial for the solar cell performance, helping the electron-hole separation.

Lafond et al. studied the most realistic substitution reactions for Cu-poor CZTS concluding that two types of defects were the most likely to be formed: \([Zn^{2+} + V_{\text{Cu}}]\) (A-type, presenting Cu poor and Zn rich composition) and \([2Zn^{2+}_{\text{Cu}} + Zn^{2+}_{\text{Sn}}]\) (B-type, presenting Cu poor and Sn poor composition) [17]. In a solid state nuclear magnetic resonance (NMR) study, Paris et al. demonstrated the presence of \([V_{\text{Cu}} + Zn_{\text{Cu}}]\) and \([2Zn^{2+}_{\text{Cu}} + Zn^{2+}_{\text{Sn}}]\) for A-type and B-Type CZTS respectively [18].

In this paper we present an investigation of the influence of the metal ratios on the properties of Cu poor CZTSe thin films absorber layers and also demonstrate how the variations in composition affect the properties of CZTSe solar cells, with the aim of improving the understanding of why Cu-poor Zn-rich compositions are also needed in CZTSSe for synthesising high efficiency solar cells.

## 2. Experimental

### 2.1. CZTSe absorber synthesis

Sets of Cu-Zn-Sn (CZT) multilayer precursor films were deposited using a Nordiko 2000 magnetron sputter deposition system with 150 mm diameter, high purity (5N) elemental targets. Molybdenum coated soda-lime glass substrates were used in all cases. Power values of 70 W and 140 W were applied to the Zn and Sn targets, respectively. Three sets of precursor were prepared by varying only the power of the Cu target resulting in CZT precursors with different Cu content. The power applied to the Cu target was 130 W, 120 W, and 110 W for the films presented in this study. For the CZT precursor deposition, the Argon pressure was \(3 \times 10^{-3}\) Torr (0.4 Pa) and the deposition time was adjusted to achieve around 450 nm CZT precursor films. The precursors were then introduced into graphite boxes together with 4 Se pellets. The graphite boxes containing the precursors and the Se pellets were then heated in a Rapid Thermal Processor (Annealsys AS-One) at 300 °C and 500 °C for 5 and 15 minutes respectively. The rate of the ramp
for both steps was 4 °C per second. The process was carried out under 85 kPa of N\textsubscript{2} base pressure.

2.2. CZTSe absorber characterisation

The CZTSe absorbers were measured with a PANalyticalX’Pert MPD Pro X-ray diffractometer in grazing incidence (GI) configuration at incident angles of 0.5, 1, and 2° using a Cu K-α radiation source (λ=0.15406 nm). Le Bail refinements of the patterns were performed using the Fullprof software package in order to determine the lattice constant values\cite{19}. The composition of the samples was determined using a FEI Quanta 200 scanning electron microscope (SEM) equipped with an Oxford Instruments energy dispersive X-ray analyser (EDX) and X-ray fluorescence (XRF) with an operating voltage of 40kV. The EDX system was calibrated using standards for quantitative analysis recommended by Oxford Instruments. The software used to perform the calibration was the Quant Optimization which is part of the INCA software package for EDX analysis. The XRF system was calibrated with reference samples measured by inductively coupled plasma mass spectrometry (ICP-MS). Raman scattering measurements were performed with 532.0 nm excitation using a LabRam HR800-UV, and 457.9 nm excitation a with T64000 Horiba-JobinYvon spectrometers.

2.3. Device fabrication and characterisation

CZTSe absorbers were etched with 10 % w KCN solution for 30 seconds. A CdS buffer layer of approximately 50nm in thickness was deposited after the etching treatment by chemical bath deposition (CBD) followed by an amorphous ZnO/ZnO:Al window layer deposited by RF sputtering. 0.028 M of cadmium acetate and 0.374 M thiourea aqueous solutions were used as the Cd and S sources respectively in the CBD process. The total volume of the solution was 0.25L. Cells of area 0.09 cm\textsuperscript{2} were mechanically scribed. Illuminated J-V curves were measured under 100mW/cm\textsuperscript{2} simulated AM1.5 solar illumination calibrated with a Si reference cell and external quantum efficiency (EQE) was measured using a lock-in amplifier and a chopped white light source (900 W, halogen lamp, 360 Hz) combined with a dual grating monochromator. The sun simulator has an UXL 553 Short arc Xenon lamp. The spectrum is matched by an AM1.5G filter and meets the class “A” standard. Both EQE and J-V measurements were performed by contacting the front contact of the solar cells directly on the TCO, since there was no metallic grid added.

3. Results and discussion

3.1. Synthesis of absorbers and characterisation
Cu-Zn-Sn metallic precursor layers were deposited on Mo coated SLG glasses as described in the experimental section. Three different compositions of precursors were used for this study. To show a clear comparison, the metal compositions of the absorber layers produced in this study are plotted in Figure 1 in the pseudo-ternary phase diagram (TPD) reported by Dudchak et al [4]. The metal atomic composition of the precursors and absorber layers was measured either by EDX at 20 kV from the top view or with XRF, and the values can be seen in Table 1. For an easier understanding of the manuscript, the samples prepared with the three different compositions will be referred as Sample 1, Sample 2 and Sample 3 as the Cu/(Zn+Sn) ratio decreases in the films and the composition moves away from the stoichiometric point in the TPD. A comparison of the composition between the precursors and the absorbers measured by XRF shows that the Cu/(Zn+Sn) ratios increase after the selenisation process. We attribute this to the loss of Zn and Sn due to the formation of volatile compounds of both constituents [20]. The Zn/Sn ratios seen for Sample 2 and Sample 3 increase after the selenisation process, indicating an increase of the Sn loss as the Cu content decreases in the precursor, as also observed by Collord et al [21].

In previous studies, we have found that EDX compositional measurements could be influenced by the presence of secondary phases on the surface such as ZnSe or Cu₅Se providing values that do not necessarily correspond to a representative average composition of the absorber layer [22]. Therefore, a combination of EDX and XRF measurements could be useful to compare and especially to make sure that the trends of composition studied are consistent. We observe differences between the two measurements. Apart for the difference in penetration depth of each technique, this variation could be attributed to several factors such as the calibration used for each method. The main difference observed between the measurements is that, for the samples of this study, in both the precursors and the absorbers, the apparent Cu content is higher when measuring with XRF. The average composition of the films measured with the two techniques follows the same variation, with the difference between them being the variation in Cu content. Qualitatively, it is possible to observe that “Sample 2” and “Sample 3” have compositions far from the stoichiometric region. The reactive annealing process used for the synthesis of the CZTSe absorbers uses fast ramping rates. This ternary phase diagram, which applies to equilibrium conditions at 400 ºC, might not be the most adequate tool for estimating the amount and presence of secondary phases in the film. However, it can provide an idea of which potential secondary phases might be present in the absorber layer and is useful for the clarity of the reader. As the Cu content in the film decreases, the compositions plotted in the TDP are located in the ZnSe-
3.2. Secondary phases and microstructure

The metal compositions of the samples are plotted along the off-stoichiometric type lines in Figure 2b. As the Cu decreases from Sample 1 to Sample 3, the points move towards the A-type line, predicting an increased in the concentration of $[V_{Cu} + Zn_{Cu}]$[17]. Raman spectra of the CZTSe absorbers synthesised measured with 532nm excitation are shown in Figure 2b. All peaks observed in the spectra are attributed to the Raman modes of the CZTSe phase [23]. For the analysis presented here, we will refer to two main peaks:

1) The most intense peak centred at 197 cm$^{-1}$ which is attributed to A symmetry mode and involves purely Se anion vibrations [24].

2) A broad peak centred at around 170 cm$^{-1}$ which could be attributed to the convolution of two A modes (corresponding to Se vibrations) and two B modes (involving mostly Cu/Zn and Cu/Sn atomic plane vibrations[25]).

The three spectra are normalised to the most intense peak at 197 cm$^{-1}$. When the Cu content is decreased in the absorber layers, the relative intensity of the peak at 170 cm$^{-1}$ decreases. It was previously observed that the intensity of this peak with respect to the A mode at 197 cm$^{-1}$ was very sensitive to the Cu content in CZTSe thin films, particularly when there was Cu deficit in the structure[26]. When the Cu/(Zn+Sn) ratio decreases and the composition moves away from the stoichiometric point towards the Cu poor region in the TPD shown in Figure 1, the relative intensity of the band at 170 cm$^{-1}$ also decreases. One possible explanation for this decrease is that it is related to an increase in the concentration of $[V_{Cu} + Zn_{Cu}]$, which has been theoretically predicted to be present in high population in Cu poor CZTSe[16]. This could decrease the intensity of the B modes appearing in this region corresponding to the vibrations of Cu/Zn and Cu/Sn atomic vibrations, as reported in[23], which would lead to the overall decrease in the intensity of the peak centred at 170 cm$^{-1}$. The inset in Figure 2b shows a magnification of the A mode at 196 cm$^{-1}$. When looking in detail at the position of this peak, one can observe that for “Sample 2” and “Sample 3” it is blue shifted in comparison to “Sample 1”. Rey et al. observed a blue shift of the A mode that could be related to an increase in the ordering in the samples of their study.[14]. In our study, this could be an indication that the two CZTSe thin films with less Cu content are more ordered than the one with composition near to the stoichiometric point. This is in agreement with the study of Paris et al. where they observed...
that Cu poor CZTS samples with predominant \([V_{\text{Cu}} + Zn_{\text{Cu}}]\) defect
clusters presented an increase in the ordering of the Cu and Zn cations in
the 2c and 2d positions[18].

Le Bail analysis was performed on the XRD patterns acquired at
different GI angles for the CZTSe absorbers. The diffractograms acquired
at a GI angle of 1° are shown in Figure 3. No secondary phases could be
detected with this technique in the absorbers of this study. This is
particularly interesting, since the composition of “Sample 2” and
“Sample 3” are far away from the stoichiometric region of CZTSe and, if
there was a quantitative presence of SnSe_x, then this technique should
indicate it. The diffraction patterns were measured with low incidence
angle of 0.5, 1 and 2° acquiring information from the near surface and
bulk region of the absorbers. This allowed us to reduce the potential
variations in the lattice parameter calculations induced by uniform strain
created by the growth of MoSe_2 at the interface with the back contact. In
addition, the acquisition of data from the near surface region ensures a
more reliable comparison with the penetration depth of the laser used for
recording the Raman spectra (~100nm). Figure 4 shows a comparison of
the lattice parameters obtained for the CZTSe absorber layers of this
study. The lattice constant \(a\) does not appear to be influenced by the
variations in composition, although the lattice constant \(c\) decreases
significantly when the Cu content in the samples is decreased. Schorr
studied the temperature behaviour of the lattice parameters of (CZTS),
where a monotonic decrease of the lattice parameter \(a\) was observed with
decreasing temperature[11]. A different behaviour was observed for \(c\),
where a kink indicating a more abrupt reduction of the lattice constant
was observed starting at around 260°C. This temperature was estimated to
be the order-disorder transition temperature of this compound [12].
Additionally, Cu/Zn disorder has been predicted to expand the unit cell
volume mainly by the increase in the value of \(c\), suggesting that an
accurate estimation of the lattice parameters can provide valuable
information related to order-disorder in CZTSSe materials. Our results
show that the lower the Cu content of the CZTSe samples, the lower is
the value of \(c\). The decrease in the value of \(c\) is in agreement with the
theory of the increase in ordering of Cu/Zn (001) planes, and as well as
the results obtained from Raman spectroscopy.

3.3. Device performance

Current-voltage characteristics values of the best devices processed with
the CZTSe absorbers with different compositions within the Cu-poor and
Zn-rich region are shown in Table 2 and in Figure 5c, d, e and f with the
average and maximum values of 9 cells measured in each sample
category. The dark and illuminated current density-voltage (J-V) curves
are represented in Figure 5a. It is possible to observe an increase in the performance of the devices when the Cu content in the absorber layer is decreased. This increase in performance is mainly driven by an increase in $V_{OC}$, from 367 mV to 434 mV. EQE measurements of the solar cells with different compositions are also presented in Figure 5b. The three devices present EQE values around 80-90 % between 500 and 900 nm. It is also possible to see interference in this range that may lead to loss in current. This is attributed to the TCO which in the case of these samples is about 700 nm thick with the aim of having a safer contact with sharp evaporated on these devices. The bandgap, Eg, of the devices is calculated from the inflection point of the decay of EQE at long wavelength. The values obtained are also shown in Table 2. This method has already been used in highly efficient CZTSSe solar cells for calculating the bandgap and for evaluating the tail profile associated with potential fluctuations and bandgap fluctuations. The derivative method was also assumed to be the most robust for the calculation of Eg values [27]. It is interesting to observe that a difference in the bandgap of around 70 meV can be found between Sample 1 and Sample 3. This difference can also explain the increase in $V_{OC}$ of around 70 mV in the case of the best cells and an increase of around 50 mV in the average values as shown in Figure 5d. $V_{OC}$ varied from 367 to 434 mV when changing composition of the best devices from Sample 1 to Sample 3, the one with the lowest Cu content of the series. A similar trend with decreasing Cu content and increasing Zn/Sn ratio has also been identified for the CZTSSe solar cells [21].

Variations in the crystal structure that CZTSSe materials adopt leads to different optoelectronic properties. In order to discuss the $V_{OC}$ increase observed in our devices, several considerations regarding the bandgap dependency with the crystal structure of CZTSSe compounds need to be taken into account. Using different calculation methods, it is found that there could be a variation of around 150 meV between CZTSe in the kesterite or stannite crystal structure [28-30]. Rey et al., in an experimental study of the order-disorder transition in CZTSe co-evaporated thin films, observed an increase in bandgap from 0.94 to 1.06 eV after an ordering procedure. It is also important to consider how different point defects generated by differences in composition could induce significant differences in the bandgap. Charge compensated defect clusters have been calculated to be present in high concentration and to highly contribute to the non-stoichiometry of CZTSe. In particular $[V_{Cu} + Zn_{Cu}]$ induces a downshift of the valence band maximum and an upshift of the conduction band minimum[16].
In the previous section, it was shown that Raman and GIXRD measurements performed in the absorber layers suggest that the concentration of [VCu + ZnCu] defect clusters increases with decreasing Cu content. This increases the order in the Cu-Zn 2c and 2d positions, thus, increasing the Eg of the CZTSe absorber layers leading to an increase in the V_{OC} of the fabricated solar cells. In addition, while the Cu content in the CZTSe absorber layers decreases and the Zn/Sn ratio increases, in theory, it has been predicted that the concentration of [2Cu_{Zn} + Sn_{Zn}] decreases, producing a downshift of the conduction band edge and inducing electron trapping, thus reducing the solar cell performance[16].

4. Conclusion

CZTSe absorber layers with a variation of Cu-poor and Zn-rich content have been synthesised in order to investigate the correlation of modifications observed in the crystal structure with the optoelectronic properties of CZTSe devices. Raman spectroscopy suggests an increase in [VCu + ZnCu] defect clusters as the [Cu/(Zn+Sn)] ratio decreases and [Zn/Sn] ratio increases. This is observed from the change in intensity of the band at around 170 cm\(^{-1}\) relative to the band at 197 cm\(^{-1}\). Le Bail analysis has been performed for the X-ray diffraction patterns of the CZTSe absorber layers in grazing incidence configuration. In the same compositional trend, while the lattice parameter a remains constant, c decreases. J-V results showed a dependence of the V_{OC} values on the Cu content ranging from 367 to 434 mV as the Cu concentration decreased in the absorbers. EQE shows that the increase in the maximum achievable V_{OC} appears to be linked to a widening of the bandgap. The best solar cell was based on the absorber layer with the lowest Cu content and yielded an efficiency of 8.1% with a fill factor of 59.8 %, J_{sc} = 31.1 mA/cm\(^2\) and V_{OC} = 434 mV. We propose that the widening of the bandgap is attributed to an increase of the concentration of the [VCu + ZnCu] defect cluster which induces ordering in the Cu/Zn (001) planes of the CZTSe. The results observed in the series of the presented devices show a good agreement with theoretical calculations regarding the influence of the defect clusters on the optoelectronic properties of CZTSSe solar cells.
