13 **Abstract**

14 Research on optimal outbreeding describes the greater reproductive success experienced on average
15 by couples who are neither too closely related, nor too genetically dissimilar. How is optimal outbreeding
16 achieved? Faces that subtly resemble family members could present useful cues to a potential
17 reproductive partner with an optimal level of genetic dissimilarity. Here, we present the first empirical
18 data that heterosexual women select partners who resemble their brothers. Raters ranked the facial
19 similarity between a woman's male partner, and that woman's brother compared to foils. In a multilevel
20 ordinal logistic regression that modeled variability in both the stimuli and the raters, there was clear
21 evidence for perceptual similarity in facial photographs of a woman's partner and her brother. That is,
22 although siblings themselves are sexually aversive, sibling resemblance is not. The affective responses
23 of disgust and attraction may be calibrated to distinguish close kin from individuals with some genetic
24 dissimilarity during partner choice.

25 **1. Introduction**

26 In selecting a partner, the most reproductively successful individuals are those that avoid partners who
27 are too closely or too distantly related, thereby avoiding both inbreeding and outbreeding (see e.g.
28 Edmands 2007). Inbreeding is biologically detrimental due to the accumulation of harmful recessive
29 genes, a reduction in useful genetic heterozygosity, the possibility of increased competitiveness
30 between similar offspring, and a reduction in offspring variability (Bateson 1983). Excessive
31 outbreeding, on the other hand, may separate genes that work well together, disrupt the inheritance of
32 traits that have been adapted to work well in the local environment, and increase the costs of altruism
33 (Bateson 1983; Rushton 1989). Empirical data that support the value of intermediate relatedness
34 ('optimal outbreeding') have been presented for many species, including humans. For example, a study
35 of all known couples born in Iceland during a 165-year period found that the optimal level of relatedness
36 in that population in terms of number of grandchildren was around the level of third or fourth cousin
37 (Helgason, et al. 2008).

38

39 How do people avoid both inbreeding and excessive outbreeding? The avoidance of inbreeding appears
40 to be operationalised by the Westermarck effect, whereby people are not sexually attracted to those
41 with whom they socialise during childhood (reviewed in Rantala and Marcinkowska 2011). An aversion
42 to siblings as sexual partners seems to develop through maternal perinatal association and co-
43 residence duration (De Smet, et al. 2014; Lieberman 2009; Lieberman, et al. 2007). To avoid excessive
44 outbreeding however, slight physical resemblance might provide an appropriate cue. Features found in
45 parental faces might be one of the most useful cues to genetic similarity, particularly in the environment
46 in which humans evolved, without frequent exposure to views of themselves in reflective surfaces. Data
47 support this: several studies have found that people choose partners and prefer faces that resemble
48 their parents (Berezkei, et al. 2002; Berezkei, et al. 2004; Dixson, et al. 2013; Heffernan and Fraley
49 2013; Jedlicka 1980; Jedlicka 1984; Little, et al. 2003; Marcinkowska and Rantala 2012; Perrett, et al.
50 2002; Rantala, et al. 2010; Saxton 2016; Seki, et al. 2012; Wilson and Barrett 1987; Zei, et al. 1981);
51 see also (Fraley and Marks 2010; Rantala and Marcinkowska 2011); but see (Nojo, et al. 2011).

52

53 However, parental appearance is an incomplete source of information. Maternal appearance provides
54 just one point of reference. Reliance on paternal faces is potentially problematic: serial relationships in

55 both traditional (Hill and Hurtado 1996) and modern societies (Cherlin 1981) mean that the father might
56 no longer be present. In addition, the putative father is not the biological father in cases that may
57 average around 2% of births worldwide (see Bressan and Kramer 2015). Sibling facial features
58 therefore could be a useful point of reference, especially given the extensive presence of siblings during
59 an individual's childhood in historically high-fertility populations. Additionally, younger brothers are more
60 readily detected as kin than older brothers (Lieberman, et al. 2007), and thus might be the better referent
61 for kin resemblance. Accordingly, our study used a multilevel ordinal logistic regression analysis to
62 investigate resemblance between a woman's partner and her brother, alongside the possible
63 moderating effects of absolute and relative age, in two separate samples.

64

65 **2. Material and Methods**

66 All of the research described herein was granted ethical approval by the Northumbria University
67 Psychology Department Ethics Committee.

68

69 *2.1 Stimuli creation*

70 Stimuli were obtained in two ways: through the provision of photographic images by consenting
71 individuals ('volunteer sample'), and by the collection of appropriate photographic images available
72 online ('online sample'). The volunteer sample consisted of 32 female participants who passed on
73 details of the study to their brother and male partner, who in turn supplied photographs of themselves.
74 The 32 brothers (aged 18 – 40; mean +/- SD = 24 +/- 5 years) and 32 partners (aged 20 – 37; mean +/-
75 SD = 23 +/- 4 years) were requested to provide good quality, recent, colour facial photographs, with a
76 neutral facial expression, although participants were often smiling in the photographs that they supplied.
77 The online sample consisted of 48 photographs (24 brothers, 24 partners) that were located online by
78 a researcher (A.N.) who had been instructed to find relatively recent facial photographs of brothers and
79 partners of public figures or celebrities. All individuals in the photographs were aged 18 or over, and
80 exact ages were identified for all but two of the siblings; 22 of the brothers were aged 21 – 53 (mean
81 +/- SD = 31 +/- 8 years), and the 24 partners were aged 22 – 50 (mean +/- SD = 34 +/- 9 years). The
82 researcher was asked to find brothers and partners who appeared to be of white ethnicity, where the
83 face of a single individual was apparent with a fairly neutral facial expression and unadorned features
84 (i.e. without glasses, make-up, etc.) The photographs had to be sourced from a site that allowed the

85 usage of photographs in research (i.e. non-commercially), and the photographs had to be taken in a
86 venue where the individual in the photograph could reasonably expect to be observed by strangers,
87 following ethical guidelines for the research use of information available online (Hewson and Buchanan
88 2013). Across the whole sample, 28 of the brothers were older than the woman whose partner's
89 photograph was in the study, and 28 of the brothers were younger (or, in one instance, a twin, who was
90 categorised here as a younger brother). Three of the men had features consistent with Asian ethnicity,
91 while all of the others appeared to be of white ethnicity. We performed an additional check of our
92 statistical model by adding a categorical term to distinguish these three men along with one man who
93 was a half brother, but found no significant effect.

94

95 The photographs were grouped into sets of four brothers and four partners, keeping separate the
96 volunteer and online sample to increase within-set consistency in photograph quality and cultural or
97 demographic variables. The photographs were grouped so that six of the sets only contained younger
98 brothers, six of the sets only contained older brothers, and two of the sets (one from the volunteer
99 sample and one from the online sample) contained a mixture (3:1) of younger and older brothers. The
100 photographs were arranged into tableaux following the methodology of previous work on preferences
101 for parental resemblance in faces (Berezkei, et al. 2002; Berezkei, et al. 2004), and printed in colour
102 on A4 sheets of paper. Photographs varied a little in size, but each was around 5cm x 6cm. Photographs
103 were cropped to focus in on the face, so typically would be cropped from just below the chin to just
104 above the top of the hair. On the right-hand side, the four photographs of the four partners in a set were
105 displayed; this set of four photographs was repeated identically across four sheets of paper. On the left-
106 hand side of these four sheets, the photograph of one of the brothers from the same set was displayed,
107 with a different brother on each of the four sheets. In addition, four versions of each of the two tableaux
108 that contained a mixture of older and younger brothers were created, so that the placement on the
109 stimulus sheet of the photograph of the single younger/older brother could be fully counterbalanced in
110 the four possible positions (top/bottom left/right). After these constraints, the selection of photographs
111 for each set was based on ordered partner age from youngest to oldest, so that the people in the
112 photographs were as similar as possible in age. The age difference between the oldest and youngest
113 of the four partners in each set ranged from 0 to 16 years, with a mean age difference of 5 years

114 between the oldest and youngest partner in each set. Age and relative age (older or younger) were
115 included as variables in the models (see below).

116

117 *2.2 Photograph rating*

118 An opportunity sample of 32 female raters aged 19 to 40 (mean +/- SD = 24 +/- 5 years) were presented
119 with the 56 tableaux in random order. Female raters were chosen because the volunteer and online
120 sample were all female, and so we wanted to focus on female facial perception. For each tableau, they
121 were asked to rank the four men on the right hand side (the partner plus three foils) in terms of their
122 similarity to the man on the left hand side (the brother). A sample size of 32 raters was selected based
123 on pilot work (see Supplementary Online Material 2). Raters were not told that the individuals in the
124 photographs were related, but only that the study was investigating perceptions of facial similarity.
125 Participants were quizzed and debriefed afterwards, and no-one reported guessing the aims of the
126 study. 23 out of a possible 1792 of the raters' responses (1.3%) were unclear (e.g. a rater listed the
127 same photo as both most and third most similar) and these were treated as missing data in the model.
128 Data were collected from one additional rater, but were discarded prior to analysis because the tableaux
129 were erroneously provided in numerical rather than randomised order, meaning that the same image
130 of the same four brothers was presented on the right-hand side of all of the first four tableaux, then the
131 same four brothers were presented on the second four tableaux, and so on.

132

133 **3. Results**

134 Rating data were modelled using multilevel ordinal logistic regression implemented in the *ordinal*
135 package (Christensen 2015) within R (<http://www.R-project.org/>). Using an ordinal model permitted us
136 to model the cumulative probability of the brother and partner being ranked as 1) most similar to each
137 other; 2) most or second most similar; and 3) most, second most or third most similar. The advantage
138 of a multilevel model is that variability in both faces and raters can be incorporated into the model as
139 fully crossed random effects. Traditional analyses that ignore variability in either faces or raters, either
140 by treating ratings as independent or by modelling variability by raters or by faces in isolation, are known
141 to inflate Type I error (see e.g. Baguley 2012; Judd, et al. 2012). Our initial model therefore included
142 two random effects (face and rater) and three intercepts representing the thresholds in the ordinal

143 logistic regression model on a log odds scale. In this intercept-only model, the estimate of face variability
144 is 1.251 while the rater variability is negligible (1.7×10^{-5}) suggesting individual differences in the
145 resemblance of brothers to partners, but near independence of rankings within raters in our sample.
146 The estimated thresholds for the ratings were -1.02, 0.34 and 1.67 corresponding to a cumulative
147 probability of .27, .59 and .84. The raters were choosing from four photos, and so if they were picking
148 at chance levels, they should have chosen the correct pair at a rate of .25. The probability of ranking
149 the brother most (.27), second (.32), or third (.26) most similar to the partner therefore appears elevated
150 relative to chance (.25), while the probability of ranking the brother least similar to the partner is
151 depressed (.16) (Figure 1).
152
153

154
155
156 **Figure 1:** Cumulative probability of ranking the correct brother-boyfriend pairing as most, second most,
157 and third most similar, while controlling for participant age and sample source (see section 2 Materials
158 and Methods and section 3 Results). Observed values (mean +/- 95% CIs) are indicated by solid vertical
159 lines, while chance values for each ranking are marked by dashed horizontal lines. A 95% CI for
160 the mean rankings are indicated as calculated using the intercept-only model (red horizontal line) and
161 under the null hypothesis of equiprobability (vertical dotted line).

162 To test whether the joint pattern of ratings was consistent with guessing we simulated a 95% CI for the
163 mean rating by parametric bootstrapping of the intercept only model (incorporating the random effects
164 of both faces and raters). This simulation (with 5000 replicated data sets) estimated the mean ranking
165 as 2.335, 95% CI [2.28, 2.39] and close to the observed mean ranking of 2.338 (to 3 d.p.). The potential
166 impact of missing data (1.3% of the expected total data; see subsection 2.2 *Photograph rating*) was
167 simulated by replacing simulated data with missing values with a fixed probability equal to that observed
168 in the real data set. This is equivalent to treating data as missing completely at random (though with so
169 few missing cases the impact on inferences is negligible). A null hypothesis test of the observed mean
170 ranking was obtained by simulating an equiprobability model (fixing the probability of each ranking at
171 0.25) with the same random effects. Under the equiprobability model the mean ranking was 2.50 ($SE =$
172 0.0287) and not consistent with the observed mean of 2.34, $z = 5.64$, $p < .0001$.

173

174 A further model was fitted to determine the influence of other variables on the rankings. This model
175 included the woman's age (centred) as a continuous predictor, and several categorical predictors:
176 brother's relative age (older or younger), partner's relative age (older or younger), and whether the
177 photo came from the volunteer sample or the online sample. All categorical predictors were effect coded
178 for this analysis and effects were tested by a likelihood ratio test. Only partner's relative age was close
179 to statistical significance, $G^2(1) = 2.76$, $p < .10$ (with other effects $G^2 < 1$). There is thus little evidence
180 that any of these variables influenced the ratings. Including these predictors also had little impact on
181 the thresholds; Figure 1 shows the cumulative probability of rating the sibling as most, second most or
182 third most similar when these predictors were included. Although stimuli were counterbalanced we also
183 checked the impact of tableaux version and position of the correct match by including version, position
184 and all version by position interactions. None of the effects reached statistical significance and the
185 overall change in fit was negligible, $G^2(15) = 10.2$, $p = .81$. As a final check we tested the hypothesis
186 that ratings were driven merely by the similarity or dissimilarity in age of the partners and brothers or of
187 the women and their brothers. To this end we added the absolute difference in ages to the model for
188 each of these comparisons; neither was close to statistical significance, $G^2 < 1$.

189

190 **4. Discussion**

191 We present clear evidence that women select partners who resemble their brothers. This is true
192 irrespective of whether the sample is based around a student or a celebrity population. People
193 experience strong aversion and disgust towards incest (Antfolk, et al. 2012). However, identity is not
194 the same as resemblance; the proper domain of kinship detecting mechanisms (Lieberman, et al. 2007)
195 might entail the creation of aversion to siblings themselves, and not to those that resemble them. Our
196 results suggest that affective responses during partner choice (disgust and attraction) could be
197 calibrated to distinguish actual close kin from those who might be somewhat genetically similar and
198 could thereby support optimum outbreeding. That is, people are disgusted by thinking about engaging
199 in relationships with siblings (Lieberman, et al. 2007), but seem to pick partners who show some slight
200 resemblance to siblings.

201

202 Facial resemblance can indicate relatedness even beyond immediate family members (Davidson 1993;
203 Kaminski, et al. 2009). Although contextual cues such as kinship nomenclature and family histories also
204 indicate relatedness, automated cue-based processes might function alongside and independently of
205 explicit knowledge, and have a deeper evolutionary history (Park, et al. 2008). Humans can detect
206 kinship on the basis of appearance similarity in mother-daughter pairs in mandrills, gorillas,
207 chimpanzees and macaques (Alvergne, et al. 2009; Vokey, et al. 2004). Non-human primates can also
208 detect visual similarity in kin (e.g. Kazem and Widdig 2013; Parr and de Waal 1999; Pfefferle, et al.
209 2014). For much of human history, a preference for partners who demonstrated subtle resemblances
210 to close family members might have supported the selection of a reproductive partner who was neither
211 too closely nor too distantly related.

212

213 Facial cues to kinship play a role in sexual, parental and social behaviours (Lewis 2011; Park, et al.
214 2008). People are more likely to trust and invest in those whose familiar facial appearance indicates
215 possible family membership (DeBruine 2005; Platek, et al. 2002). As attraction affects every level of
216 interpersonal interaction, our results also suggest a possible mechanism by which nepotism could be
217 scaffolded. Although we focussed on women's choices, the same tendencies should apply to men.
218 Indeed, men might find sibling-resemblance less aversive than women do (Marcinkowska, et al. 2013),
219 and this can be explained by men's lesser reproductive investment and hence lower risk in a sub-
220 optimal partner (Haig 1999).

221

222 Siblings resemble parents, and individuals have been previously shown to select partners who resemble
223 their parents. Our work suggests that the effect sizes for each are similar (see Supplementary Material
224 1); parents and siblings could both provide reference points. Zebra finches (Kruijt, et al. 1983), snow
225 geese (e.g. Cooke, et al. 1976; Cooke and McNally 1975; Walter 1973), bullfinch (Nicolai 1956), and
226 mallards (Klint 1978) demonstrate preferences for sibling characteristics that are independent of
227 preferences for parental characteristics. Siblings might provide a source of information on familial
228 resemblance that is more extensive than that provided by parents. Future research should contrast
229 parental, sibling and self resemblance explicitly, in order to parse their contributions to partner choice.

230

231 Previous research that has looked at the effects of siblings on attractiveness judgements of facial
232 images does not support the interpretation that sibling resemblance unambiguously enhances
233 judgements of attractiveness *per se*. One previous research study investigated the impact of sibling-
234 resemblance on attraction by computer-manipulating facial images so that they resembled the raters'
235 siblings or the raters themselves. The study found that men rated sibling-resembling faces as
236 significantly more attractive than self-resembling faces but not significantly different from control faces,
237 whereas women rated sibling-resembling faces as significantly less attractive than control faces and no
238 different from self-resembling faces (Marcinkowska, et al. 2013). Men with sisters have been found to
239 be less likely to judge feminised women's faces attractive than men without sisters do (Marcinkowska,
240 et al. 2016), although in contrast, adolescent boys in a single-sex school environment (i.e. with limited
241 daytime visual exposure to girls) have been found to judge female facial femininity as more attractive if
242 they have sisters than if they do not (Saxton, et al. 2009). Attractiveness judgements assessed in a
243 laboratory context may not always map directly onto patterns of relationship formation and maintenance
244 when other factors come into play.

245

246 One limitation of our study was that the photographs were not fully standardised; they portrayed facial
247 features, but also facial expressions, hairstyles, and some elements of clothing and background. We
248 reduced the possible impact of these elements as much as possible by asking participants to provide
249 standardised photographs, by cropping photographs to focus on the face, and by presenting the raters
250 with photographs from the online sample separately from the volunteer sample (see Material and

251 Methods section). We asked the raters to judge facial similarity, but these non-standardised elements
252 likely contributed somewhat to their decisions. Therefore, it is possible that our raters were not matching
253 the photographs merely on facial structural similarity, but also on elements such as emotionality
254 (perceived through facial expressions), and socio-economic status and cultural cues (perceived through
255 clothing and hairstyle). Nevertheless, we note that previous research that used non-standardised
256 photographs (Berezkei, et al. 2002; Berezkei, et al. 2004) to examine similarity between individuals'
257 partners and their parents revealed similar results to research that used standardised photographs
258 (Vukovic, et al. 2015). Future research might undertake the logistically more complicated step of
259 creating standardised photographs of all participants.

260

261 Our study focussed on contemporary western populations. Although our biologically-based hypotheses
262 should apply cross-culturally, other cultures remain to be tested. Indeed, we found substantive inter-
263 individual variability in the extent to which a woman's brother and partner were similar: not all women
264 select partners who resemble their brothers. Accordingly, the effect will be weaker in contexts that
265 amplify the variables that reduce preferences for brother-resemblance. We did not find that older
266 compared to younger brothers had differential effects. Future research might investigate other possible
267 individual predictors of brother-partner similarity, such as emotional closeness between brother and
268 sister (Berezkei, et al. 2002; Berezkei, et al. 2004). However, here we demonstrate perceptual
269 similarity between women's brothers and partners in a contemporary population.
