Abstract. Organic carbon (OC) stored in Arctic permafrost represents one of Earth's largest and most vulnerable terrestrial carbon pools. Amplified climate warming across the Arctic results in widespread permafrost thaw. Permafrost deposits exposed at river cliffs and coasts are particularly susceptible to thawing processes. Accelerating erosion of terrestrial permafrost along shorelines leads to increased transfer of organic matter (OM) to nearshore waters. However, the amount of terrestrial permafrost carbon and nitrogen as well as the OM quality in these deposits is still poorly quantified. We define the OM quality as the intrinsic potential for further transformation, decomposition and mineralisation. Here, we characterise the sources and the quality of OM supplied to the Lena River at a rapidly eroding permafrost river shoreline cliff in the eastern part of the delta (Sobo-Sise Island). Our multi-proxy approach captures bulk elemental, molecu-

lar geochemical and carbon isotopic analyses of Late Pleistocene Yedoma permafrost and Holocene cover deposits, discontinuously spanning the last ~ 52 kyr. We showed that the ancient permafrost exposed in the Sobo-Sise cliff has a high organic carbon content (mean of about 5 wt %). The oldest sediments stem from Marine Isotope Stage (MIS) 3 interstadial deposits (dated to 52 to 28 cal ka BP) and are overlaid by last glacial MIS 2 (dated to 28 to 15 cal ka BP) and Holocene MIS 1 (dated to 7–0 cal ka BP) deposits. The relatively high average chain length (ACL) index of *n*-alkanes along the cliff profile indicates a predominant contribution of vascular plants to the OM composition. The elevated ratio of iso- and anteiso-branched fatty acids (FAs) relative to mid- and long-chain ($C \geq 20$) *n*-FAs in the interstadial MIS 3 and the interglacial MIS 1 deposits suggests stronger microbial activity and consequently higher input of bacterial biomass during

these climatically warmer periods. The overall high carbon preference index (CPI) and higher plant fatty acid (HPFA) values as well as high C/N ratios point to a good quality of the preserved OM and thus to a high potential of the OM for decomposition upon thaw. A decrease in HPFA values downwards along the profile probably indicates stronger OM decomposition in the oldest (MIS 3) deposits of the cliff. The characterisation of OM from eroding permafrost leads to a better assessment of the greenhouse gas potential of the OC released into river and nearshore waters in the future.

1 Introduction

Climate warming puts permafrost, especially ice-rich permafrost, in the terrestrial Arctic at risk of thawing (e.g. Strauss et al., 2021b). Permafrost, by definition, is ground that stays below 0 °C for 2 or more consecutive years. Terrestrial permafrost ecosystems are affected by ongoing climate warming with consequences for geomorphological, hydrological and biogeochemical processes from a local to regional scale (IPCC, 2019). Almost twice as much carbon is stored in the permafrost region than what is currently contained in the atmosphere (Hugelius et al., 2014; Mishra et al., 2021), making permafrost carbon dynamics a globally relevant issue (Grosse et al., 2011; Schuur et al., 2008; Strauss et al., 2021a; Turetsky et al., 2020). Total estimated soil organic carbon (SOC) storage for the permafrost region is $\sim 1100\text{--}1600$ Gt, of which 181 ± 54 Gt is attributed to deep permafrost (below 3 m depth) of the Yedoma region (Hugelius et al., 2014; Strauss et al., 2021b, 2013).

Warming throughout the Arctic prolongs the season for permafrost thaw and open ice-free water bodies, resulting in increasing erosion of ice- and carbon-rich permafrost sediments exposed at coasts (Günther et al., 2013; Jones et al., 2020). Very ice-rich permafrost deposits (i.e. 50–90 vol % ice) such as the Late Pleistocene Yedoma Ice Complex (Schirrmeister et al., 2013; Strauss et al., 2017) are particularly vulnerable to rapid thermo-denudation and thermo-erosion processes along river shores (Costard et al., 2014; Kanevskiy et al., 2016; Stettner et al., 2018; Fuchs et al., 2020). Vonk et al. (2013b) showed that Yedoma ice-wedge meltwater can increase the decomposition of organic matter (OM) due to co-metabolising effects. Another potential impact of the decomposition of terrestrial OM and discharge with Arctic river water is the change in biochemical properties that may increase ocean acidification and anthropogenic carbon dioxide uptake from the atmosphere (Semiletov et al., 2016). Furthermore, Semiletov et al. (2016) estimated that 57 % of the terrestrial organic carbon in the East Siberian Shelf originates from ancient Pleistocene-age permafrost C, such as Yedoma deposits adjacent to river or coastal zones. Extensive river networks like the Lena River, especially in their delta zones, carry large nutrient OM loads

to the nearshore zone and onto the Arctic Shelf (Mann et al., 2022; Sanders et al., 2022). The Arctic river discharge has increased significantly in recent decades, transporting organic-rich waters to the nearshore area (Holmes et al., 2012, 2021). Increased riverbank erosion of Arctic rivers following warming during the last few decades constitutes an important mechanism of carbon export from land to water (Zhang et al., 2017, 2021; Fuchs et al., 2020). The studies cited here stress the need to better understand the interactions between thawing permafrost and river and nearshore waters.

The study of fossil biomolecules and other OM characteristics provides insights into the composition and level of OM decomposition and hence can greatly improve estimates of the greenhouse gas potential of thaw-mobilised OM from permafrost deposits (Andersson and Meyers, 2012; Sánchez-García et al., 2014). A few studies have previously focused on molecular biomarkers in north-eastern Siberian permafrost deposits (e.g. Zech et al., 2010; Höfle et al., 2013; Strauss et al., 2015; Stapel et al., 2016; Jongejans et al., 2020). In general, the abundance and distribution of *n*-alkanes, which are long-chained, single-bond hydrocarbons, are used for OM characterisation where the chain length of *n*-alkanes indicates OM sources.

In our study, we measure molecular biomarkers (*n*-alkanes, *n*-fatty acids) and use established biomarker proxies and indices such as the average chain length (ACL) of *n*-alkanes, the carbon preference index (CPI) and the higher plant fatty acid (HPFA) index to test whether they mirror the OM degree of decomposition and reflect the OM quality in ancient permafrost deposits. Additionally, analyses of the total organic carbon content (TOC), the stable carbon isotope ratios ($\delta^{13}\text{C}$ of TOC), the total nitrogen (TN) content and TOC/TN (here referred to as the C/N ratio) are applied to our sample set. Hierarchical clustering is used to identify the stratigraphical units along the sample profile based on the major changes in OM composition.

Thus, the OM characteristics of permafrost deposits, rapidly eroding at a cliff site in the eastern Lena Delta, are analysed for the first time for biomarkers. The set of frozen samples was obtained along a 25 m vertical cliff profile with a relatively high sampling density of about 1 m covering all exposed cryostratigraphic units. In this study, we aim (1) to characterise the OM composition of ancient permafrost that accumulated under different climate conditions; (2) to assess the degree of decomposition that the OM already experienced; and (3) to hypothesise, based on the decomposition legacy, the potential of future decomposability and microbial decomposition of the permafrost OM.

2 Study area

The Lena River forms the largest delta in the Arctic, covering an area of 29×10^3 km² (Schneider et al., 2009), and discharges the second-highest freshwater load into the Laptev

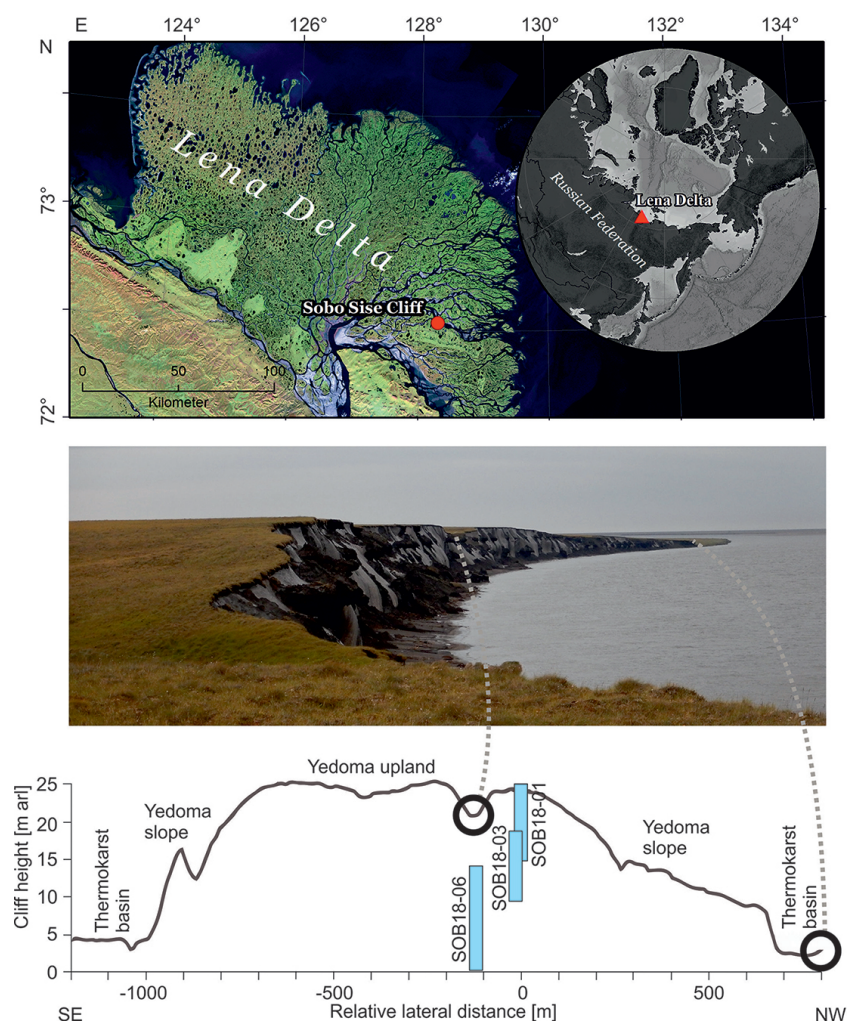

Figure 1. Overview of the Sobo-Sise Yedoma cliff. (a) Location of the Sobo-Sise Yedoma cliff in the Lena Delta in north-eastern Siberia (Landsat 5 mosaic (band combination 5, 4, 3) including scenes from 2009 and 2010; Landsat 5 image courtesy of the US Geological Survey); (b) picture of the Sobo-Sise Yedoma cliff from the east to west; (c) cross-section of the cliff profile (adapted from Wetterich et al., 2020a) indicating the three vertically sampled sections: SOB18-01, SOB18-03 and SOB18-06.

Sea, with a mean annual discharge of $525 \text{ km}^3 \text{ yr}^{-1}$ (Holmes et al., 2021). It also transports summer “heat” from the south to the north (Yang et al., 2005). The study area on Sobo-Sise Island (Fig. 1a–b) is located in the continuous permafrost zone. The island stretches between the Sardakhskaya and Bykovskaya main channels in the eastern part of the delta. In addition to the modern floodplain, there are three geomorphic units in the delta (Grigoriev, 1993; Schwamborn et al., 2002). While the first unit consists of Holocene floodplains and could occur in the whole delta area, the second unit consists of Late Pleistocene and Holocene fluvial deposits that are mostly located in the north-western part of the delta and are cut off from the current delta dynamics (Schirrmeister et al., 2011b). The third geomorphological unit consists of erosional remnants of a Late Pleistocene accumulation plain with ice-rich Yedoma Ice Complex deposits and is present

mainly in the west, south and east of the delta (Schwamborn et al., 2002; Wetterich et al., 2008; Morgenstern et al., 2011). According to a landform classification for Sobo-Sise Island, 43 % of the land surface is occupied by Yedoma uplands and Yedoma slopes and 43 % is thermokarst basins with the remaining 14 % being thermokarst lakes (Fuchs et al., 2018). The terrain is affected by thermokarst processes (Nitze and Grosse, 2016) and surface thaw subsidence (Chen et al., 2018).

The distinct surface morphology of Sobo-Sise Island includes Yedoma uplands intersected by thermo-erosional valleys and thermokarst basins. Syngenetic permafrost formation in polygonal tundra landscapes over long periods in the Late Pleistocene formed thick deposits with large ice wedges that are exposed at the cliff (Schirrmeister et al., 2011b, 2020; Strauss et al., 2015; Jongejans et al., 2018). Schirrmeister

et al. (2011b) attributed parts of the third geomorphological unit in the Lena Delta in the western and southern parts of the delta to remnants of a Yedoma accumulation plain. This formed during the Late Pleistocene when the Lena River had its delta farther north. Radiocarbon ages corroborated that Yedoma deposits on Sobo-Sise Island accumulated during the Late Pleistocene between about 52 and 15 cal ka BP. Substantial hiatuses were found at about 36–29 cal ka BP and at 20 to 17 cal ka BP, which may be related to fluvial erosion and/or changed discharge patterns of the Lena River (Wetterich et al., 2020a). Middle to Late Holocene ages from 6.36 to 2.5 cal kyr BP were found in the uppermost cover deposits of the cliff, which is also in agreement with other cover deposits found on top of Yedoma such as on the nearby Bykovsky Peninsula (Schirrmeister et al., 2002; Grosse et al., 2007).

The Sobo-Sise Yedoma cliff has an average height of 22 m with a maximum height of 27.7 m above the river water level (m a.r.l.) (Fuchs et al., 2020) and is affected by fluvio-thermal erosion. The current average shoreline retreat rate, which was calculated using satellite data, is 15.7 m yr^{-1} (2015–2018), which is remarkably high (Fuchs et al., 2020). In comparison, retreat rates were lower for other Yedoma cliffs such as on Kurungnakh Island in the central Lena Delta ($4.1\text{--}6.9 \text{ m yr}^{-1}$; Stettner et al., 2018) and at the Itkillik exposure in Alaska (11 m yr^{-1} ; Kanevskiy et al., 2016) but even higher for Muostahk Island (29.4 m yr^{-1} ; Günther et al., 2013) and Cape Mamontov Klyk (21 m yr^{-1} ; Günther et al., 2015). The Sobo-Sise Yedoma cliff ($72^{\circ}32' \text{ N}$, $128^{\circ}17' \text{ E}$; Fig. 1c) extends over 1660 m in length and faces north towards the Sardakhskaya Channel. Here, the water discharge amounts to about $8000 \text{ m}^3 \text{ s}^{-1}$ during the summer-low period (Fedorova et al., 2015) and the Lena River is ice-covered for about 8 months per year between October and May. The river ice thickness reaches up to 2 m. Water depth at the beginning of the Sardakhskaya Channel (close to Stolp and Sardakh islands) can reach up to 22 m (Fedorova et al., 2015) and is approximately 11 m in front of the Sobo-Sise Yedoma cliff, allowing for water flow underneath the river ice cover during the winter months (Fuchs et al., 2020).

3 Methods

3.1 Sample collection

The Sobo-Sise Yedoma cliff was sampled in three overlapping vertical sediment profiles (Fig. 1b) covering the entire exposed permafrost section (profile SOB18-01, 24.1 to 15.7 m a.r.l.; profile SOB18-03, 18.2 to 10.2 m a.r.l.; profile SOB18-06, 13.4 to 0.9 m a.r.l.). Each profile was cryolithologically described (see Wetterich et al., 2018, 2020a), and samples were collected at 0.5 m intervals by rappelling down on a rope from the top of the cliff. We used an axe and hammer to extract defined cubes of frozen ground

($\sim 20 \times 10 \times 10 \text{ cm}$) from the cliff wall. Samples were collected after cleaning and scraping off the outermost unfrozen and frozen parts of the cliff wall in order to collect frozen, uncontaminated samples. Then, the samples were lifted upwards, cleaned and subsampled for biomarker analysis. In total, we collected 61 sediment samples, of which 28 were selected for biomarker analysis at about 1 m intervals covering the entire exposed section. The samples were stored frozen in pre-combusted glass jars, apart from 9 samples (SOB18-06-09 to SOB18-06-34) which were initially stored in plastic whirl packs before being transferred in a frozen state to glass containers after transport to the laboratories.

3.2 Sedimentological organic matter parameters

Prior to bulk geochemical analyses, all samples were freeze-dried (Sublimator, ZIRBUS technology), ground and homogenised (Fritsch PULVERISETTE 5 planetary mill; 8 min at 360 rotations per minute). Total elemental carbon (TC) and total nitrogen (TN) content of sediment samples in weight percentage (wt %) were measured with a carbon–nitrogen–sulfur analyser (vario EL III, Elementar) with a detection limit of 0.1 wt % for carbon and nitrogen. Samples below this detection limit were set to 0.05 wt % so that the statistics could be calculated. Total organic carbon (TOC) content in weight percentage (wt %) was measured with a TOC analyser (vario MAX C, Elementar; analytical accuracy of 0.1 wt %). The TOC to TN (C/N) ratio has been used as a rough first indicator of the degree of OM decomposition with decreasing values indicating proceeding decomposition (Palmtag et al., 2015). The stable carbon isotope ratio ($\delta^{13}\text{C}$) of TOC reflects both the initial contribution from different plant species and plant components and OM decomposition processes (Gundelwein et al., 2007). Samples for $\delta^{13}\text{C}$ analyses were treated with hydrochloric acid (20 mL, 1.3 M) to remove carbonates, heated on a hotplate (97.7°C for 3 h) and subsequently washed with distilled water. The samples were filtered (Whatman Grade GF/B, nominal particle retention of $1.0 \mu\text{m}$), after which the residue was dried and ground. All $\delta^{13}\text{C}$ samples were measured using a DELTA V Advantage isotope ratio mass spectrometer (MS) equipped with a Flash 2000 analyser (Thermo Fisher Scientific; analytical accuracy of 0.15 ‰), using helium as a carrier gas. The $\delta^{13}\text{C}$ ($^{13}\text{C}/^{12}\text{C}$) value is reported in per mille (‰) compared to the standard ratio Vienna Pee Dee Belemnite (VPDB).

3.3 Lipid biomarker analyses

Lipid biomarkers provide information on a molecular level about the source of OM, the environmental conditions during deposition and the degree of decomposition. In this study, we focused on *n*-alkanes in the aliphatic OM fraction and *n*-fatty acids in the polar hetero-compound fraction. Changes in their relative abundance can provide an indication of the degree of decomposition (Kim et al., 2005) as outlined below. We anal-

used the *n*-alkane distributions of all 28 samples and selected 13 samples for the analysis of *n*-fatty acids. The selection of the *n*-fatty acids was made to cover the entire profile continuously (approximately every 2 m).

3.3.1 Extraction and fraction separation

Following freeze-drying and grinding, biomarker subsamples were transferred into glass jars. Extraction and separation were conducted according to Schulte et al. (2000) and Strauss et al. (2015). Samples were processed in two batches, each containing 14 samples. We weighed between 8 and 11 g in extraction cell bodies fit for the accelerated solvent extractor (ASE 200 Dionex). Dichloromethane / methanol (volume ratio of 99 : 1) was used as a solvent mixture for OM extraction. Each sample was held in a static phase (5 min heating phase, 20 min at 75 °C and 5 MPa). Dissolved compounds were then further concentrated at ~ 42 °C using a closed-cell concentrator (TurboVap 500 Zymark), and the remaining solvent was evaporated under N₂. Afterwards, internal standards were added: 5 α -androstane for the aliphatic fraction, ethylpyrene for the aromatic fraction, 5 α -androstan-17-one for the NSO (nitrogen, sulfur and/or oxygen) neutral polar fraction and erucic acid for the NSO fatty-acid fraction (80 μ L each from respective 100 μ g mL⁻¹ standard solutions). Subsequently, an asphaltene precipitation was performed to remove compounds with higher molecular complexity (asphaltenes) by dissolving the extracts in a small amount of dichloromethane and adding a 40-fold excess of *n*-hexane. Precipitated asphaltenes were removed by filtration through a sodium-sulfate-filled funnel. Subsequently, the *n*-hexane-soluble portion was separated by medium-pressure liquid chromatography (MPLC) (Radke et al., 1980) into three fractions of different polarities: aliphatic hydrocarbons, aromatic hydrocarbons and polar hetero-compounds (NSO compounds). Finally, the NSO fractions of 13 samples were split into an acid and neutral polar (alcohol) fraction using a KOH-impregnated column. While the *n*-fatty-acid potassium salts were attached to the silica gel, the neutral polar compounds were eluted with dichloromethane. After remobilising the *n*-fatty acids by protonation of their salts with formic acid, the *n*-fatty-acid fraction was obtained with dichloromethane.

3.3.2 GC-MS measurements and compound quantification

n-Alkanes and *n*-fatty acids were analysed using gas chromatography coupled with a mass spectrometer (GC-MS; GC – Trace GC Ultra and MS – DSQ, both Thermo Fisher Scientific). Prior to the analyses, *n*-fatty acids were methylated with diazomethane. The GC was equipped with a cold injection system operating in the splitless mode. The injector temperature was programmed from 50 to 300 °C at a rate of 10 °C s⁻¹. Helium was used as carrier gas with a con-

stant flow of 1 mL min⁻¹. After injection, the compounds of interest were separated on an SGE BPX5 fused-silica capillary column (50 m length, 0.22 mm i.d., 0.25 μ m film thickness) using the following temperature conditions: initial temperature of 50 °C (1 min isothermal), heating rate of 3 °C min⁻¹ to 310 °C, held isothermally for 30 min. The MS operated in the electron impact mode at 70 eV. Full-scan mass spectra were recorded from *m/z* 50–600 at a scan rate of 2.5 scans s⁻¹. Using the software Xcalibur (Thermo Fisher Scientific), peaks in the GC-MS run were quantified using the internal standards for *n*-alkanes and *n*-fatty acids. All biomarker concentrations are expressed in micrograms per gram of dry sediment (μ g g⁻¹ sed.) and per gram of TOC (μ g g⁻¹ TOC).

3.4 Lipid biomarker indices

3.4.1 Average chain length

The *n*-alkane average chain length (ACL) is the weighted average number of carbon atoms used for determining OM sources. Long-chain odd-numbered *n*-alkanes (*C* \geq 21) are essential constituents that serve as biomarkers for higher terrestrial plants (Eglinton and Hamilton, 1967; Eglinton and Eglinton, 2008; Schäfer et al., 2016), whereas shorter chain lengths indicate bryophyte, bacterial or algal origin (Cranwell, 1984; Rieley et al., 1991; Kuhn et al., 2010). A change in the ACL can suggest a change in the terrestrial source biota. We used the equation (Eq. 1) first described by Poynter (1989) but with a chain interval from C₂₃ to C₃₃ following Strauss et al. (2015) and Jongejans et al. (2018):

$$\text{ACL} = \frac{\sum i \cdot C_i}{\sum C_i}, \quad (1)$$

where *C* denotes concentration and *i* the carbon number.

3.4.2 Carbon preference index

The CPI (carbon preference index) was originally introduced by Bray and Evans (1961) as the ratio of odd- to even-numbered *n*-alkanes and indicates the level of OM transformation, which decreases with progressing maturation. OM decomposition leading to lower CPI values is a measure of thermal alteration referring to rocks or oils on a geological timescale. However, this ratio, as well as the very similar odd-over-even predominance (OEP) ratio, was previously used in Quaternary permafrost deposits as an indicator for OM decomposition (Zech et al., 2009; Strauss et al., 2015; Struck et al., 2020; Jongejans et al., 2020). Based on these studies, we refer to values over 5 as less degraded OM of high quality. Equation (2) describes the CPI and was modified after Marzi et al. (1993) using C_{23–33} as a chain length interval.

$$\text{CPI}_{23-33} = \frac{(\sum \text{odd } C_{23-31}) + (\sum \text{odd } C_{25-33})}{2(\sum \text{even } C_{22-32})} \quad (2)$$

Figure 2. Biogeochemical parameters of the Sobo-Sise Yedoma cliff: total organic carbon (TOC) content, total nitrogen (TN) content, carbon-to-nitrogen (C/N) ratio, bulk stable carbon isotope ratios ($\delta^{13}\text{C}$), radiocarbon ages and modelled age in calibrated kiloyears before present (cal kyr BP). Data points are displayed over cliff height from the cliff top at 25 m above river level (a.r.l.) to cliff bottom at 0 m a.r.l. The three sections of SOB18 are plotted separately for each parameter (black, dark grey and light grey circles). Units I, II (grey rectangle) and III correspond to Marine Isotope Stage (MIS) 1 to 3, respectively. The radiocarbon ages were published in Wetterich et al. (2020a).

3.4.3 Higher plant fatty acids

For each sample, the absolute *n*-fatty-acid (FA) concentration was measured and the most abundant homologue's chain length was identified. In addition, we looked at the share of iso- and anteiso-branched FAs, which are indicators for microbial biomass (Rilfors et al., 1978; Stapel et al., 2016). Furthermore, we calculated the higher plant fatty acid (HPFA) index, which is the relative amount of the long-chain *n*-fatty acids to long-chain *n*-alkanes in the sediments. The HPFA index was introduced by Strauss et al. (2015) following the principles of the HPA index of Poynter (1989), only with using fatty acids instead of wax alcohols (Eq. 3). The HPFA index reflects the degree of preservation of OM due to the higher lability of *n*-fatty acids in relation to *n*-alkanes (Canuel and Martens, 1996). The preferential decomposition of fatty acids is due to their functional group leading to a chemical polarisation within the molecule forming an attack point for geochemical or microbiological decomposition and/or decarboxylation (Killops and Killops, 2013). Therefore, a decrease in the HPFA index indicates increased OM decomposition. We use this index for internal comparison where higher values (above the mean) indicate a comparatively higher-quality OM.

$$\text{HPFA} = \frac{\sum n - \text{fatty acids } \text{C}_{24}\text{C}_{26}\text{C}_{28}}{\sum n - \text{fatty acids } \text{C}_{24}\text{C}_{26}\text{C}_{28} + \sum n - \text{alkanes } \text{C}_{27}\text{C}_{29}\text{C}_{31}} \quad (3)$$

3.5 Data analysis

In order to identify the stratification along the cliff based on the OM characteristics of the permafrost sediments, the data set was clustered using a constrained agglomerative hierarchical clustering of a distance matrix (chclust of the rjoja package, in R version 4.0.4) (Juggins, 2019). We applied the non-parametric Kruskal–Wallis (> two groups) test for statistical analyses of the data to compare all major parameters (TOC, C/N, *n*-alkanes, ACL, CPI, short and long *n*-fatty acids, HPFA index, and (iso- + anteiso-branched) / (mid- and long-chain *n*-fatty acids)) between the identified clusters. In the Results section, we report the *p* values; the correlation coefficients are reported in the Supplement (Table S1).

4 Results

The uppermost sediments of the cliff consisted of Holocene-age sediments (from 24.1 to 22.5 m a.r.l.; upper part of SOB18-01) on top of Late Pleistocene Yedoma sediments from 22.2 m a.r.l. down to the cliff base at the river water level. A detailed cryostratigraphic description is given in Wetterich et al. (2020a).

4.1 Sedimentological organic matter parameters

TOC content was highest in the topmost sample and ranged from < 0.1 wt % (below the detection limit, sample SOB18-01-18 at 15.7 m a.r.l.) to 25.5 wt % (SOB18-01-01 at 24.1 m a.r.l.). Both the minimum and the maximum TOC values were found within profile SOB18-01 (Fig. 2). The average TOC content was 4.9 wt % (standard deviation (SD) 4.7, $n = 28$) and values decreased from the cliff top downwards with two values higher than 10 wt % at 24.1 m a.r.l. (SOB18-01-01; 25.5 wt %) and at 16.2 m a.r.l. (SOB18-03-05; 11.3 wt %). TN content had an average of 0.3 wt % (SD 0.2), and the highest value was also found at 24.1 m a.r.l. (SOB18-01-01; 0.8 wt %) and the lowest at 15.7 m a.r.l. (SOB18-01-18; < 0.1 wt %). C/N ratios ranged from 7.2 to 30.5 (Fig. 2) and displayed, except for the uppermost sample, only little variability over the cliff profile with a mean of 13.2 (SD 4.2). The $\delta^{13}\text{C}$ values ranged from -25.2‰ (SOB18-01-12 at 18.7 m a.r.l.) to -29.4‰ (SOB18-03-05 at 16.2 m a.r.l.) and had an average of -27.2‰ (SD 1.1). There was a significant negative correlation between $\delta^{13}\text{C}$ and C/N values ($r = -0.59$ (Pearson correlation), $p < 0.01$). Radiocarbon ages of selected plant remains were determined on a MICADAS system. These data and a Bayesian age-depth model were published by Wetterich et al. (2020a). The laboratory methods were described in detail by Mollenhauer et al. (2021). The radiocarbon ages ranged from 2.50 (at 23.7 m a.r.l.) to 51.88 cal kyr BP (at 0.9 m a.r.l.).

4.2 Biomarkers

4.2.1 *n*-Alkanes

n-Alkanes were detected in the range between *n*-C₁₄ and *n*-C₃₅ and showed a strong odd-over-even carbon number predominance. The relative *n*-alkane concentration increased in the lower part of the cliff, closer to the river level. Relative *n*-alkane concentrations ranged from 1 to 172 $\mu\text{g g}^{-1}$ TOC (mean 30, SD 42) for the short-chain (C₁₄ to C₂₀) *n*-alkanes and from 119 to 3214 $\mu\text{g g}^{-1}$ TOC (mean 1068, SD 886) for the long-chain (C₂₁ to C₃₃) *n*-alkanes (Fig. 3). The absolute concentrations were also higher in the lower part of the cliff for the short-chain (mean 1 $\mu\text{g g}^{-1}$ sed., SD 1) and long-chain *n*-alkanes (mean 41 $\mu\text{g g}^{-1}$ sed., SD 31). The main dominating *n*-alkane chain length was *n*-C₂₇ in the lower part of the cliff and alternated between *n*-C₂₇ and *n*-C₂₉ in the upper part (Fig. S1). Four samples were dominated by the *n*-C₃₁ *n*-alkane.

The *n*-alkane-based ACL showed variations between 27.1 (SOB18-06-19 at 4.5 m a.r.l.) and 29.0 (SOB18-01-06 at 21.7 m a.r.l.) with a mean of 28.0 across the cliff (SD 0.50; Fig. 3). The CPI of *n*-alkanes (*n*-C₂₃ to *n*-C₃₃) ranged from 5.76 (SOB18-06-15; 6.5 m a.r.l.) to 16.29 (SOB18-06-05; 11.5 m a.r.l.) with a mean value of 9.89 (SD 2.79). Below 7 m a.r.l., the CPI significantly decreased.

4.2.2 *n*-Fatty acids

We found *n*-FAs with carbon numbers between C₈ and C₃₂. The *n*-FAs showed a strong even-over-odd carbon number predominance. Furthermore, hydroxy FAs (C₆ to C₈), iso-branched FAs (C₁₀ to C₁₉), anteiso-branched FAs (C₁₁, C₁₂, C₁₃, C₁₅ and C₁₇), monounsaturated FAs (C₁₆ to C₂₀ and C₂₄), unsaturated iso- and anteiso-branched FAs (C₁₇), cyclopropyl FAs (C₁₇ and C₁₉), di- and triunsaturated FAs (C₁₈), and phytanic acid were detected (Fig. S2, Table S2). Concentration of long-chain *n*-FAs (C₂₄ to C₃₂) ranged from 290 $\mu\text{g g}^{-1}$ TOC at 24.1 m a.r.l. to 2346 $\mu\text{g g}^{-1}$ TOC at 1.4 m a.r.l. (mean 1041 $\mu\text{g g}^{-1}$ TOC, SD 655). The most abundant long-chain *n*-FA was *n*-C₂₄ for all samples, except at 16.7 m a.r.l. (*n*-C₂₆) (Figs. 2 and S2). The mid-chain *n*-FA (C₂₁ to C₂₃) concentration ranged from 121 to 1250 $\mu\text{g g}^{-1}$ TOC (mean 463 $\mu\text{g g}^{-1}$ TOC, SD 314) and was highest at 22.7 m a.r.l. The short-chain *n*-FA concentration (C₈ to C₂₀) ranged from 120 to 968 $\mu\text{g g}^{-1}$ TOC (mean 560 $\mu\text{g g}^{-1}$ TOC, SD 212) and was highest in the bottom sample at 1.4 m a.r.l. Among the short-chain FAs, the *n*-C₁₆ dominated all samples (Fig. S2). The iso- and anteiso-branched FAs were more abundant in the bottom section of the cliff and lowest in the middle section, and the ratio of iso- and anteiso-branched saturated fatty acids (C₁₁, C₁₃, C₁₅ and C₁₇) to mid- and long-chain ($C \geq 21$) *n*-FAs ranged from 0.03 to 0.32 (mean 0.13, SD 0.09; Figs. 3 and S2). The HPFA index had a mean value of 0.63 (SD 0.11, $n = 13$), a minimum of 0.45 (SOB18-06-17 at 5.5 m a.r.l.) and a maximum of 0.86 (SOB18-01-04 at 22.7 m a.r.l.) close to the cliff top. Overall, HPFA values below 16 m a.r.l. were slightly lower than in the upper section.

4.3 Clustering

We identified three main sub-groups using agglomerative hierarchical clustering (Fig. 4a): unit I from 24.1 to 22.7 m a.r.l. ($n = 3$), unit II from 21.7 to 16.7 m a.r.l. ($n = 7$) and unit III from 16.2 to 1.4 m a.r.l. ($n = 18$). Our clustering matched the three cryostratigraphic units as defined by Wetterich et al. (2020a), which further corresponded to MIS 1, MIS 2 and MIS 3 from the top to the bottom. The TOC content (Fig. 4b) and C/N ratio were significantly the highest in unit I and lowest in unit II ($p < 0.01$ and $p < 0.05$, respectively; Fig. 2 and Table S1). The short-chain (C₁₄ to C₂₀) and long-chain (C₂₁ to C₃₃) *n*-alkane concentration, expressed in $\mu\text{g g}^{-1}$ TOC, was higher in unit III, but the differences were only significant for the short-chain *n*-alkanes ($p < 0.01$) (Fig. 4c). The short-chain (C₈ to C₂₀), mid-chain (C₂₁ to C₂₃) and long-chain (C₂₄ to C₃₂) *n*-fatty-acid concentrations expressed in $\mu\text{g g}^{-1}$ TOC did not differ significantly between the units. The ACL and CPI values were similar for each unit (Fig. 3). The HPFA index was significantly different between the units ($p < 0.05$) with the highest values in unit I and lowest values in unit III (Fig. 4d). The share of iso- and anteiso-branched

Figure 3. Biomarker parameters of the Sobo-Sise Yedoma cliff. The first four columns show *n*-alkane parameters: short-chain (C_{14} – C_{20}), and long-chain (C_{21} – C_{33}) *n*-alkane concentrations (both in $\mu\text{g g}^{-1}$ TOC), the *n*-alkane average chain length (ACL_{23–33}), and *n*-alkane carbon preference index (CPI_{23–33}). The last five columns show *n*-fatty-acid parameters: short-chain (C_8 – C_{20}), mid-chain (C_{21} – C_{23}) and long-chain (C_{24} – C_{32}) *n*-fatty-acid concentrations (in $\mu\text{g g}^{-1}$ TOC); the ratio of iso- and anteiso-branched saturated fatty acids (C_{11} , C_{13} , C_{15} and C_{17}) to mid- and long-chain ($C \geq 21$) *n*-fatty acids; and the higher plant fatty acid (HPFA) index. Data points are displayed over cliff height from the cliff top at 25 m above river level (a.r.l.) to cliff bottom at 0 m a.r.l. The three sections of SOB18 are plotted separately for each parameter (black, dark grey and light grey circles). Units I, II (grey rectangle) and III correspond to Marine Isotope Stage (MIS) 1 to 3.

FAs compared to mid- and long-chain *n*-FAs was highest in unit III and lowest in unit II (Fig. 4e), but the differences were not significant.

5 Discussion

5.1 Terrestrial organic matter at the interface between permafrost and river

5.1.1 Organic matter source

We found that the *n*-alkane distributions were dominated by the long-chain *n*-alkanes ($C \geq 21$) and that short-chain *n*-alkanes only played a marginal role (Fig. S1). The most abundant *n*-alkane homologues in the entire data set were *n*- C_{27} , *n*- C_{29} and *n*- C_{31} , which indicates that the OM stemmed from higher land plants (Eglinton and Hamilton, 1967). This is confirmed by the dominance of long-chain *n*-FAs (C_{24} – C_{32}) with a strong even-over-odd carbon number predominance (Fig. S2). The relatively high ACL across the cliff (Fig. 3) indicates a predominant contribution of vascular plants, which corroborates the pollen record presented by Wetterich et al. (2021). Their results indicated the presence of tundra–steppe vegetation during MIS 3–2, while MIS 1 pollen spectra of the uppermost three samples indicated a shift from tundra–steppe to shrub–tundra vegetation. Occasional warmer-than-today summers were recorded during the early MIS 3 as well as the presence of low-centre polygons with favourable (stable) aquatic conditions during MIS 3.

Cooler and drier summer conditions as well as unstable (draining and rewetting phases) aquatic conditions were reconstructed for MIS 2 (Wetterich et al., 2021). In our study, the elevated ratio of iso- and anteiso-branched FAs relative to mid- and long-chain ($C \geq 21$) *n*-FAs in unit I (MIS 1) and III (MIS 3) compared to unit II (MIS 2; Figs. 4e and S2) suggests stronger microbial activity during the warmer MIS 3 and MIS 1 periods (Rilfors et al., 1978; Stapel et al., 2016) and points to a higher input of bacterial biomass during that time. Additionally, we found a significant abundance of short-chain FAs, especially *n*- C_{16} in all samples (Fig. S2). However, these FAs are common not only in bacterial but also in eukaryotic microorganisms (Gunstone et al., 2007) and thus represent a mixing signal. Therefore, we focused here on iso- and anteiso-branched FAs as they are more specific biomarkers for bacterial biomass (Kaneda, 1991).

The source and nature of the OM preserved in permafrost influence both its quantity and its quality (Jongejans et al., 2018). TOC, TN, C/N and $\delta^{13}\text{C}$ variations result from changes in biomass productivity and/or decomposition, from different OM sources, from changes in depositional conditions influencing OM preservation, and from different characteristics of Cryosol formation. Generally, enriched $\delta^{13}\text{C}$ and low TOC and C/N values, as we found in unit II and III (Fig. 2), are typical of Yedoma deposits that formed during cold stages (Schirrmeister, 2012). However, climate variations during the last ice age were differentiated into warmer interstadials (e.g. MIS 3) and colder stadial periods (e.g. MIS 2) which climatically triggered changes in vegetation and Cryosol formation. At the Sobo-Sise Yedoma cliff, the

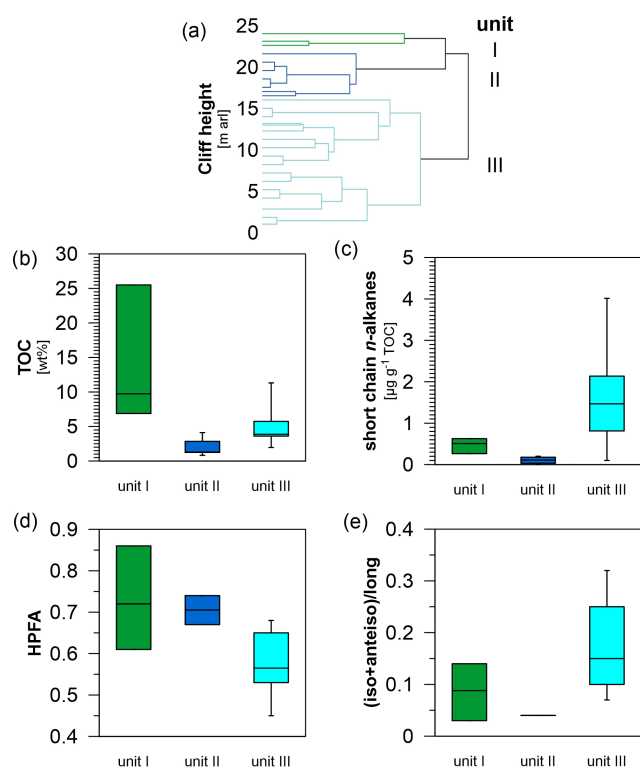

Figure 4. Statistical separation of the Sobo-Sise Yedoma cliff profile and selected carbon parameters of the separated cliff units. (a) Clustering of samples with y axis representing cliff height from the cliff top at 25 m above river level (a.r.l.) to cliff bottom at 0 m a.r.l. Unit I corresponds to Marine Isotope Stage (MIS) 1, unit II to MIS 2 and unit III to MIS 3. Resulting box plots allow better visualisation of the OM distribution along the Sobo-Sise Yedoma cliff profile: (b) total organic carbon (TOC) content (in wt %), (c) short-chain *n*-alkane concentration (in µg g⁻¹ TOC), (d) higher plant fatty acid (HPFA) index, and (e) ratio of iso- and anteiso-branched saturated fatty acids (C₁₁, C₁₃, C₁₅ and C₁₇) to mid- and long-chain (C ≥ 21) *n*-fatty acids.

TOC values were higher during MIS 1 and 3 compared to the last glacial (MIS 2) deposits, suggesting higher OM accumulation, which was presumably triggered by higher biomass production. The TOC values from the MIS 3 and MIS 2 sediments of the Sobo-Sise Yedoma cliff (< 0.1 wt %–11.3 wt %, mean 4.0 wt %) were significantly higher ($p < 0.01$) than those of other Siberian Yedoma sites (< 0.1 wt %–27 wt %, mean 3.0 wt %; 17 study sites, 719 samples) but very similar to data from Kurungnakh Island (mean 3.8 wt %) which is located about 70 km west-south-west of Sobo-Sise Island in the central Lena Delta (Strauss et al., 2012, 2020). Likely, the high TOC values in the Sobo-Sise record are a result of past wetter conditions leading to the formation of peat layers. Comparably to the Kurungnakh Island Yedoma record, the Sobo-Sise Yedoma cliff is characterised by silty sediments with multiple layers enriched in peat pointing to palaeosol formation during permafrost aggradation. The MIS 3 de-

posits contained rather less decomposed twigs and grass remains as well as single peaty lenses (15–20 cm in diameter) and peat layers (10–20 up to 130 cm thick). A similar occurrence of single-twig remains (2–4 mm in diameter), dark brown spots, finely dispersed organic remains and peaty lenses (5–25 cm in diameter) was found in MIS 2 deposits, while MIS 1 deposits contained many more peaty components, i.e. numerous peaty lenses (2–25 cm in diameter), which was reflected in higher TOC values compared to MIS 3 and MIS 2 deposits (Wetterich et al., 2020a).

At 16.2 m a.r.l., we found a peak in TOC (11.3 wt %, SOB18-03-05) and a simultaneously depleted $\delta^{13}\text{C}$ value (−29.4 ‰). High TOC and low $\delta^{13}\text{C}$ values have been found to be indicative for peat accumulation and low decomposition under wetter conditions in a more anaerobic regime (Wetterich et al., 2009; Schirrmeister et al., 2011a; Strauss et al., 2012). These peat layers can form by moss accumulation which is hardly decomposed and/or incorporated soon upon accumulation. From a biomarker perspective, this sample was not much different regarding the biomolecular composition, indicating a similar organic biomass (Fig. S2). The higher relative abundance of iso- and anteiso-FAs relative to mid- and long-chain FAs in this sample may point to increased microbial activity and thus microbial decomposition during the time of deposition in this OM-rich sample. Considering palaeoenvironmental studies from Kurungnakh Island in the central Lena Delta, palaeosol formation was intensified by relatively warm and wet summers during the climate optimum of the interstadial MIS 3 between 40 and 32 ka BP (Wetterich et al., 2008, 2014). Therefore, it is very likely that this layer is a buried palaeosol layer containing peaty material.

5.1.2 Organic matter quality

OM from different vegetation types was incorporated from the active layer into the permafrost during and after different phases of decomposition. The biogeochemical and biomarker proxies outlined in the previous section mainly describe the sources and composition of permafrost OM. In addition, biomarker ratios provide information on the decomposition level of the OM and, with that, the potential “decomposability” (quality) of the respective permafrost OM upon thaw. The OM assessment of this study via agglomerative clustering found an overall high OM quality of the Sobo-Sise Yedoma deposits with high CPI values (mean 9.89) and higher C/N ratios (mean 13.24) compared to the other Yedoma deposits such as those on the Buor Khaya Peninsula (central Laptev Sea) with mean C/N values of about 10 (Strauss et al., 2015). The elevated C/N value in the top sample of the Sobo-Sise record likely results from the influence of modern plants rooted in the active layer. For the rest of the profile, the C/N ratios were rather uniform. The high CPI in our study is comparable to other Yedoma sites as reported by Strauss et al. (2015) for the Buor Khaya Peninsula (mean

11.6) and Jongejans et al. (2018) for the Baldwin Peninsula (western Alaska; 12.2). At the Sobo-Sise Yedoma cliff, the CPI values scattered around a mean of 9.89 and decreased in the lowermost 7 m of the cliff profile. This could probably indicate a higher level of OM decomposition for the lower cliff part but can also be influenced by the vegetation type and species prevailing during the early MIS 3 with stagnant water and partly warmer-than-today summer climate conditions (Wetterich et al., 2021). The HPFA values (0.45–0.86, median 0.61) are a bit higher compared to Yedoma deposits investigated by Strauss et al. (2015) on the Buor Khaya Peninsula (0.15–0.69, median 0.54). Overall, the HPFA significantly decreased downwards (Fig. 4d; $p < 0.05$), especially below unit II, which suggests that the OM is further decomposed downwards. This fits the assumption that there was more time for OM decomposition for the older lower cliff parts of the palaeo-active layer. A higher decomposition for the lower cliff part is also supported by the highest ratio of the iso- and anteiso-branched FAs vs. mid- and long-chain FAs in the MIS 3 deposits (Fig. 4e), indicating a higher relative amount of microbial biomass and suggesting higher microbial activity during this warmer interval.

Previous studies showed that mineral-associated OM can make up a substantial fraction of the OM in permafrost soils, which protects the OM from decomposition (Dutta et al., 2006; Mueller et al., 2015). We found that the biomarker concentrations are negatively correlated with the mean grain size published by Wetterich et al. (2020b) (Fig. S3). Especially the negative correlation between the grain size and the short- ($p < 0.01$), mid- and long-chain n -FA concentrations ($p < 0.05$) are significant. This suggests that, even though the n -FAs are generally vulnerable with respect to decomposition, the n -FAs might to some extent be protected from OM decomposition upon mobilisation and transport. On top of the preferred decomposition of short-chain n -alkanes over their long counterpart (Elias et al., 2007), the stronger negative correlation (even though not significant) between the grain size and the long-chain n -alkanes compared to their short-chain counterpart could suggest that the latter might be more vulnerable to decomposition or might reflect the different sources of these biomolecules. While long-chain n -alkanes are derived from higher land plants and enter the soil by deposition, short-chain n -alkanes might contain a significant portion of microbial biomass, whose abundance depends on the availability of appropriate substrates.

As outlined above, three stages of permafrost aggradation on Sobo-Sise Island linked to climatic variability were identified according to Wetterich et al. (2020a). OM preservation during these stages is strongly impacted by the duration of freezing and thawing periods, the associated presence and absence of oxygen in the soil, the related level of microbial activity, and/or physical protection of the OM by the inorganic matrices (e.g. Fe complexation) (Freeman et al., 2001; Hedges and Keil, 1995; Lützow et al., 2006). As these factors are all closely interlinked, it is almost impossible to decipher

the control of these processes on the finally preserved OM biomarker signatures.

5.2 Implications

Nitzbon et al. (2020) found that terrestrial permafrost-locked OC will be significantly thaw-affected by 2100, and it could even be up to 3-fold (12-fold) more under warming scenario RCP4.5 (RCP8.5) compared to previous estimates if including thermokarst-inducing processes. Deep OM as characterised in our study can be released by deep disturbance processes such as thermokarst development, thermal erosion or riverbank erosion. Our findings show that freshly thawed and high-quality OM was frozen in the cliff sediments and is now being mobilised rapidly as is shown by the high annual erosion rates of 15.7 m yr^{-1} as reported by Fuchs et al. (2020) (2015–2018, in the long term 9 m yr^{-1}). Furthermore, we suggest that the very ice-rich cliff wall sections are not exposed to aerobic conditions for very long time periods before being eroded into the Lena River. Thus, aerobic microbial decomposition of the OM at the cliff front is presumably playing only a minor role. Additionally, cliff erosion is mainly driven by thermo-erosion and niche formation at the base of the ice-rich Yedoma cliff, resulting in block failure instead of slow gradual cliff retreat (Fuchs et al., 2020). Accordingly, some of the OM in the cliff may not even become exposed to the air and thaw at all before being eroded into the river. Fuchs et al. (2020) showed an average loss of $5.2 \times 10^6 \text{ kg OC yr}^{-1}$ and $0.4 \times 10^6 \text{ kg N yr}^{-1}$ (2015–2018). For the OC flux sourced from permafrost and peat deposits (and in particular from erosive locations like our study site on Sobo-Sise Island), Wild et al. (2019) estimated $0.9 \times 10^8 \text{ kg C yr}^{-1}$.

By using a biomarker approach (e.g. n -alcohols, n -fatty acids, n -alkanes) on sub-aquatic sediments, van Dongen et al. (2008) found a lower degree of decomposition of the old terrestrial OM released by the great eastern Arctic rivers, including the Lena River, compared to the western Eurasian Arctic. Thus, they predicted greater remineralisation rates and release of carbon dioxide and methane. Our biomarker findings of terrestrial permafrost fit well into this scenario. Winterfeld et al. (2015) studied the lignin phenol composition of the Lena River, Lena Delta and Laptev Sea nearshore zones and proposed that OM decomposition is considerable after permafrost thawing on land and during transport and sedimentation in the water. The present study on the OM origin and the annual OC erosion rates at the Sobo-Sise Yedoma cliff complements ongoing research on mobilisation of permafrost-locked carbon from Late Pleistocene Yedoma deposits, while thermal erosion is a widespread and climate-sensitive phenomenon in the Yedoma domain, covering nearly $5 \times 10^5 \text{ km}^2$ in Siberia and Alaska (Strauss et al., 2021b). This indicates the high potential of thermal erosion for mobilisation and release upon thaw of not only large amounts of carbon but also well-preserved OM into

the aquatic system of the Lena Delta and nearshore Laptev Sea and Arctic Ocean areas, which will affect local but likely also regional biogeochemical cycles in the marine realm (Grotheer et al., 2020; Tanski et al., 2021; Mann et al., 2022) and the shelf seas. Once mobilised and transported into inland waters, permafrost-derived OC can be rapidly used by aquatic microorganisms, increasing OM decomposition in riverine and coastal Arctic waters (Vonk et al., 2012, 2013a, 2015; Drake et al., 2015; Mann et al., 2015). Vonk et al. (2012) studied the organic matter exported from the fast-eroding Yedoma cliff of Muostakh Island, which is located about 120 km south-east of the Sobo-Sise Yedoma cliff. They found that decomposition of Yedoma OM prior to delivery to the ocean was substantial. In their study of OM mobilisation by retrogressive thaw slumps in Canada, Bröder et al. (2021) found that the majority of the exported OC was derived from permafrost deposits. However, they also found that Pleistocene permafrost deposits mostly contained less labile, slowly cycling permafrost OC. Similarly, Bröder et al. (2019) showed that more than half of the carbon transported and deposited on the shelf sea floor likely resists decomposition on a centennial scale while the rest decays relatively slowly. Furthermore, OM mobilised from Pleistocene or Holocene permafrost by rapid thermokarst and mass-wasting processes contribute different shares of particulate and dissolved organic matter (Kokelj et al., 2021; Shakil et al., 2020), which has implications for decomposition and transport. In addition, Karlsson et al. (2011) hypothesised that Yedoma OC, associated with mineral-rich matter from coastal erosion, is ballasted and thus quickly settles to the bottom. Increasing thermokarst and mass-wasting processes, as well as river and coastal erosion, will continue to mobilise both labile and recalcitrant OM from Pleistocene permafrost deposits, and it is still largely unknown what short- and long-term effects this will have on the release of greenhouse gases and alteration of biochemical processes in nearshore waters.

6 Conclusions

Sedimentological and biogeochemical analyses showed that the sediments exposed at the Sobo-Sise Yedoma cliff contain a high TOC content (mean 5 wt %) and well-preserved OM (C/N mean 13.2, mean CPI 9.89) in comparison to other Yedoma permafrost sites. Our study corroborated the palaeoenvironmental data from the Sobo-Sise Yedoma cliff from previous research which suggested that Yedoma formation during the interstadial MIS 3 and the accumulation of the topmost Holocene deposits (MIS 1) were associated with more microbial activity than during the stadial MIS 2. In addition, our findings suggest that mainly high-quality OM has been freeze-locked perennially into permafrost during the Late Pleistocene to Holocene. Although the OM quality seems to be overall fairly high (TOC, C/N and CPI), biomarker parameters indicate a higher level of OM decom-

position for the bottom 7 m (CPI) or even for the bottom 15 m (HPFA) of the cliff profile of MIS 3 age, and less OM accumulation during MIS 2 in contrast to the warmer MIS 3 and 1 sequences is assumed. At the Sobo-Sise Yedoma cliff, representing an example of rapidly eroding permafrost shorelines in the Lena Delta, OM with a high decomposition potential is being mobilised from almost all sections of the cliff profile. This material is suggested to rapidly enter the fluvial and probably also the offshore aquatic ecosystem. Thus, OM mobilisation at the Sobo-Sise Yedoma cliff and similarly eroding permafrost sites bear the potential to impact the carbon dynamics, the biogeochemistry, and the riverine and nearshore marine ecosystems.

Data availability. The data presented in this study are freely available in the PANGAEA data repository (<https://doi.org/10.1594/PANGAEA.935672>, Haugk et al., 2022). Cryolithological and geochronological data from the Sobo-Sise Yedoma cliff are available in PANGAEA (<https://doi.org/10.1594/PANGAEA.919470>, Wetterich et al., 2020b).
