13 **Abstract**

14 This paper presents the results of two-dimensional electrical resistivity tomography (ERT) of
15 permafrost developed in coastal zone of Hornsund, SW Spitsbergen. Using the ERT inversion results,
16 we studied the 'sea influence' on deeper parts of the frozen ground. The study builds on previous
17 ground temperature measurements conducted in several boreholes located in study area, which
18 captured the propagation of ground heat waves from the base of permafrost. Our resistivity models
19 indicate a major differentiation in terms of resistivity of permafrost in the coastal zone. The resistivity
20 measures obtained reveal exceptionally low resistivity in deepest layers of permafrost at the coast and
21 continuing further inland. We interpret this inversion as the result of seawater temperature and salinity
22 influences affecting the basal layers of permafrost. Based on repeat ERT surveys, two years apart,
23 we detect significant changes in the distribution of resistivity, within both the surface and basal active
24 layers, dependent on the thermal, physical and chemical characteristics of seawater. Finally, strong
25 morphological control is seen into govern the spatial patterns of behavior within the surface and basal
26 active layers and potentially influence coastal susceptibility to storm events.

31 **Introduction**

32 Surprisingly, only a few observations to date exist regarding the role of permafrost on
33 High Arctic coastal evolution (e.g. McCann and Hannell 1971). In many High Arctic
34 fjords, coastal permafrost is relatively young, having developed after deglaciation and
35 isostatic sea-level fall, and is often divided by taliks. Consequently, the influence of
36 permafrost on coastal development is less clear than along the ice-rich permafrost
37 coasts of Siberia and Alaska where older permafrost has controlled coastal evolution
38 for several hundred thousand years (Wetterich et al. 2008; Schirrmeister et al. 2010;
39 Kienast et al. 2011, Overduin et al. 2014). Nevertheless, permafrost and permafrost-
40 related processes may affect polar beach sediment budgets and is the second most
41 important agent in modification of micro-relief, after sea-ice (Trenhaile 1997). The
42 presence of permafrost is effective in protecting beach sediments from erosion. Cox
43 and Monde (1985) calculated that under the same wave conditions, frozen gravel
44 berms erode up to 10 times more slowly than an unfrozen gravel berm. The spatial
45 distribution of coastal permafrost and its transition to submarine permafrost under the
46 High Arctic fjords seafloor is largely unexplored, although several studies exist that
47 detail the thermal state of the beach and intertidal zone. For instance, McCann and
48 Hannell (1971) monitored development of the active layer across the High Arctic
49 intertidal zone in Cornwallis and Devon Islands. Between 1967–69, they observed
50 that in several profiles the depth of the active layer increased slowly toward the low
51 water mark, but it was not significantly deeper than the active layer above high water
52 mark.

53 Despite over a century of permafrost research in Spitsbergen, the thickness, type
54 (continuous, discontinuous) and thermal state of coastal permafrost have not been
55 sufficiently studied. One of the first permafrost depth calculations in Spitsbergen was
56 conducted by Werner Werenskiold (1922) who calculated that in front of flat coastal

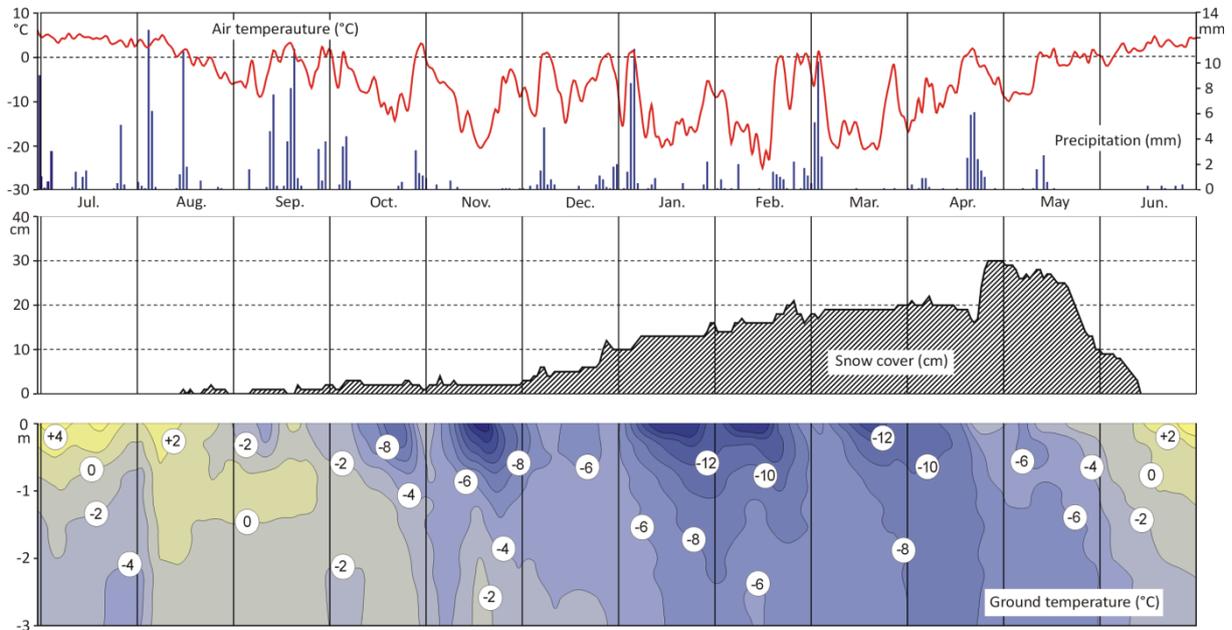

57 zones (tidal flats, barrier coasts), permafrost should reach 100 m below sea level.
58 Werenskiold (1922) suggested that in case of fjord systems, only in those with widths
59 exceeding 400 m would have had conditions enabling thawing of the fjord bottom.
60 More recent calculations concerning the permafrost thickness and detailed field
61 surveys have helped geothermal gradients – about 2–2.5°C/100 m in central
62 Spitsbergen (e.g. Liestøl 1976, Péwé 1979; Humlum et al. 2003). Instrument data on
63 the thermal state and thickness of Spitsbergen permafrost has been obtained from
64 ground temperature measurements in deep boreholes (Oberman and Kakunov 1978,
65 Isaksen et al. 2001, Harris et al. 2009, Christiansen et al. 2010). However, to our
66 knowledge, the majority of boreholes used in permafrost monitoring studies in
67 Svalbard are located inland (in valley and slope systems) and hence do not record
68 changes in thermal state of intertidal zone or submarine slopes. In general, the
69 permafrost thickness in Spitsbergen is stated to be from less than 100 m in the
70 coastal zone up to 500 m in highlands (Humlum *et al.* 2003). In this paper we adopt
71 the definition of coastal permafrost presented by Gregresen and Eidsmoen (1988)
72 during their pilot study of the thermal state of shoreface in Svea and Longyearbyen
73 as a ‘warm permafrost’, developing within a transition zone between frozen and
74 unfrozen ground. Data on Spitsbergen’s coastal permafrost has been provided by
75 measurements of ground electrical resistivity conducted by Harada and Yoshikawa
76 (1996, 1988) who specified that the permafrost thickness under delta deposits in
77 Adventfjorden is closer to 30 m. Important advances to permafrost base
78 investigations have also been provided by research on subpermafrost groundwater
79 systems (e.g. Haldorsen et al. 1996, Booij et al. 1998, Haldorsen et al. 2010, Ploeg et
80 al. 2012).

81 Difficulties with drilling through permafrost are likely to have limited the attention of
82 researchers mainly to the permafrost active layer. Over last 50 years numerous
83 investigations of active layer development and thermal state have been carried out in
84 western and central Spitsbergen i.e. Baranowski (1968); Jahn (1982); Grześ (1985);
85 Migala (1994); Leszkiewicz and Caputa (2004); Christiansen and Humlum (2008);
86 Rachlewicz and Szczuciński (2008); Westermann et al. (2011); Dolnicki et al. (2013);
87 and Byun et al. (2014). It has also been suggested that increasing permafrost
88 degradation associated with marine processes may be expected, primarily along
89 coastal lowlands, with rising temperatures (Etzelmüller et al. 2011).

90 **Sea influences on permafrost**

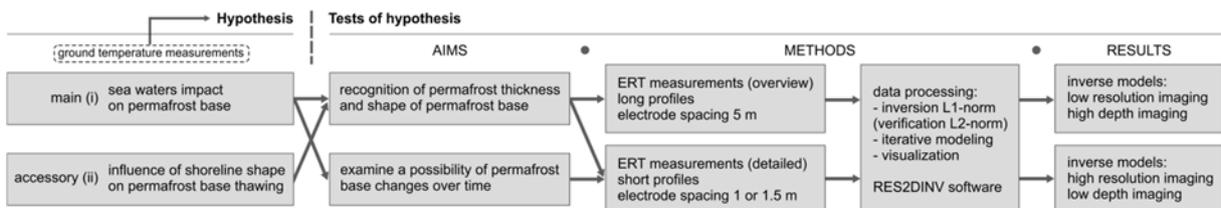

91 Previous studies on the thermal state of permafrost in the vicinity of the Polish Polar
92 Station in Hornsund by Alfred Jahn (1982) and year-round measurements (31 July
93 1986 – 29 June 1987) conducted by Krzysztof Migala (Chmal et al. 1988) have
94 highlighted the importance of sea influence on spatial distribution. Temperature
95 measurements in a 3 m deep borehole (Fig. 1) identified the occurrence of episodic
96 heat waves in the winter. The appearance of heat waves was thought to be
97 associated with the landward propagation of heat from the sea or the thermal state
98 (warm) of underground waters. However, evidence supporting such hypotheses has
99 not been provided. It is worth noting that observations described by Chmal et al.
100 (1988) are not isolated. Similar phenomena in the area of Hornsund have been
101 described by Baranowski (1968). In a 1.6 m deep borehole, he noticed an increase of
102 ground temperature at the end of May 1958, demonstrating some heat supply from
103 the bottom. Baranowski (1968) explained the fact with the seepage of seawaters
104 through a loose structure of marine terrace non longer protected by shore ice and
105 pancake ice. In the beginning of May 1958 the average temperature of the coastal

106 waters was 0.35°C , and was slightly higher than the ground temperature, and by
 107 2.2°C higher than the air temperature at the altitude of 2 m above the ground. The
 108 temperature difference measured between the fjord water temperature (up to 2.9°C)
 109 and the temperature of deeper ground sections (on the level -1.6 m) was 5°C .

110
 111 Fig. 1. Ground temperature changes in 3 m borehole drilled in the vicinity of the Polish Polar
 112 Station in Hornsund during winter 1986–1987 (after Chmal et al. 1988, modified).

113
 114 Since Baranowski’s study (1968) the concept of ‘reversed’ active layer induced by
 115 landward heat wave from warmer sea water has never been sufficiently tested and
 116 clarified. Therefore the purpose of this pilot study was to determine if the proximity of
 117 sea affects thermal state and spatial distribution of permafrost using geophysical
 118 methods. The scheme of our investigations is presented in **Figure 2**.

119
 120 Fig. 2. The scientific plan of ERT investigations of coastal permafrost in Hornsund.

121

122 We started our search for ‘coastal impact’ on permafrost during pilot electrical
123 resistivity tomography (ERT) measurements conducted across coastal zones of
124 Hyttevika and Steinvika, small rocky bays located along northern coast of Hornsund.
125 The results of pilot survey from summer 2012 proved a potential usefulness of the
126 ERT method in detection both the thickness of permafrost in the coastal zone and
127 shape of permafrost base. Analysis of pilot results led to determination of two
128 research hypotheses:

- 129 (i) the impact of seawater (temperature, salinity) may cause one-year changes in
130 the shape of the (coastal) permafrost base similar to those observed in active
131 layer;
- 132 (ii) the impact of seawater on inland permafrost depends on the coastal zone
133 shape (stronger influence on the shape of permafrost body in headlands
134 exposed to the open sea than in embayments).

135 To test our hypotheses we run the second measurement campaign in summer 2014,
136 when in addition to profiles in Hyttevika and Steinvika the measurements were
137 conducted in a third bay – Veslebogen. We understand that the ERT results, however
138 relatively suggestive, do not provide direct evidence of permafrost base thawing,
139 such as ground temperature monitoring (Dobiński 2011). Nevertheless, based on the
140 experience of other authors using the ERT in permafrost research (see references in
141 *Methods*) we believe that the method is very helpful in determining the permafrost
142 base shape in the coastal zone.

143

144 **Methods**

145 Electrical resistivity tomography (ERT) is one of the near-surface geophysics which is
146 commonly utilised in non-invasive ground investigation (e.g. Samouëlian et al., 2005,
147 Schrott and Sass, 2008, Van Dam, 2012, Loke *et al.* 2013). ERT is frequently applied
148 in projects focusing on detection of permafrost and various forms of ground ice (e.g.
149 MacKay 1969, King and Seppälä 1987, Seguin et al. 1988, Hauck 2002, Ishikawa
150 2004, Yoshikawa et al. 2006, Krautblatter and Hauck 2007, Kneisel *et al.*, 2008,
151 Harris *et al.* 2009, Hilbich *et al.* 2009, Kneisel, 2010, Lewkowicz *et al.* 2011,
152 Watanabe *et al.* 2012, Hauck 2013, You et al. 2013, Kneisel *et al.* 2014).

153 The essence of ERT are resistivity measurements (R) in several four-electrode meter
154 circuits where an electrical current (I) is passed into the ground through two
155 electrodes (C_1 , C_2), and the voltage – potential difference (V) is measured across a
156 second pair of electrodes (P_1 , P_2). As the rock mass is not a homogeneous body,
157 measured resistivity, expressed in the relation of the voltage to the current with
158 factor (k) dependent on the electrode array and distances between the electrodes, is
159 an apparent resistivity. Shifting the measurement sequences along the profile and
160 enlarging the distances between the electrodes enable achieving many measuring
161 points located in separate horizons. For achieving both a good vertical resolution and
162 depth penetration the Wenner-Schlumberger electrode array was used (Loke 2000,
163 Milsom 2003, Reynolds 2011). In order to conduct geophysical measurements the
164 ARES equipment was utilised (GF Instruments, Brno, Czech Republic).

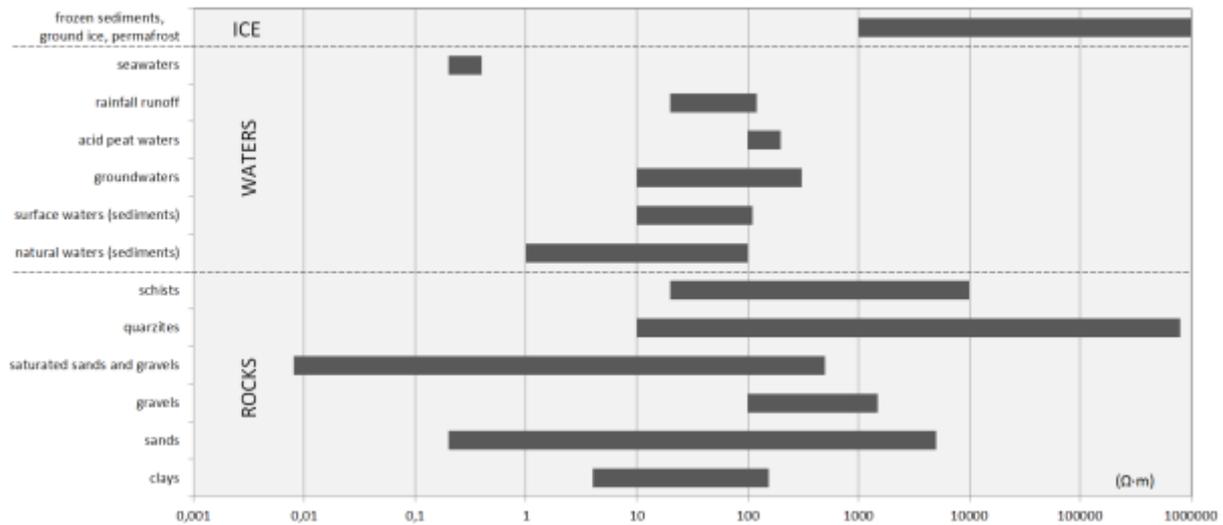

165 The field measurements were carried out in summer seasons 2012 (5th –8th August)
166 and 2014 (15th – 29th of July). Surveys were made across modern gravel-dominated
167 beaches and raised marine terraces. Each of the seven profiles was led
168 perpendicularly to the coastline and started from the water edge. The measurements
169 were made during the low tide in order to detect spatial distribution of coastal

170 permafrost in the intertidal zone. The ERT profiles were divided into the lower
171 resolution ones, but longer and deeper reaching (Profiles S1, H1, V1, V2, electrodes
172 spacing 5 m), and profiles with higher resolution, detailing the longer profiles parts
173 (Profiles S2, S3, H2, electrodes spacing 1 or 1.5 m). During measurements in 2012,
174 5 sections of active multi-electrode cables were at disposal, allowing for simultaneous
175 connection of 40 electrodes. In 2014, 8 cable sections with 64 terminals were used
176 simultaneously. Long profiles with smaller distance between the electrodes were
177 achieved by application of the *roll-on* technique, which allows continuation of
178 measurement with multiple transmission of the initial section of cables connecting the
179 electrodes to the end of the profile. Profile V1 was run across coastal zone in an
180 embayment (Veslebogen) and profile V2 across headland (between Veslebogen and
181 Ariebukta) in order to check the strength of the coastline shape factor on the coastal
182 impact on permafrost. Profiles S2 and S3 in Steinvika were led along the same profile
183 line repeated in two-year intervals to test potential changes in the permafrost base.

184 The results of electrical resistivity of the base (expressed in Ω m) were subjected to
185 standard geophysical interpretation (inversion) in the RES2DINV software (Geotomo,
186 Malaysia). The default smoothness-constrained inversion formulation was used by
187 the RES2DINV (last squares inversion). Measuring points with undoubtedly wrong
188 values were eliminated from the data received. Errors were related to physical
189 problems with the operation of the equipment in the field and weak contact of some
190 electrodes with the base (Manual for RES2DINV 2013). The default smoothness-
191 constrained inversion formula was used (least squares inversion, initial Damping
192 factor = 0.160, minimum Damping factor = 0.015). Resulting models of this L1-norm
193 inversion scheme were compared with the models achieved from the L2-norm
194 (robust) inversion method, because the robust method reduced the effects of “outlier”

195 data points where the noise comes from errors or equipment problems (Loke 2013).
196 Another analysed issue was the distribution of the percentage difference between the
197 logarithms of the observed and calculated apparent resistivity values and the points
198 with large errors were removed (above 100 percent in root mean square error
199 statistics).

200 Iterative modelling techniques produce electrical tomograms of the geological strata.
201 Logarithmic contour intervals were used for graphic visualization of these inversion
202 results. To enable a direct visual comparison of the values of three topography
203 results, they were matched using a homogenous colour scale. The colour scale was
204 constructed in a way that warm colours represent low resistivity rates (unfrozen
205 ground), and cold colours represent high resistivity rates (frozen ground). Inversion
206 models included information concerning the land surface topography. A distorted
207 finite-element grid was used (distortion damping factor 0.75), where an effect of the
208 topography is reduced with depth (Loke 2013). The geological and geomorphological
209 interpretation of inversion results was based on the terrain mapping of landforms and
210 sediments covering coastal plain and analysis of geological map (Czerny et al. 1992)
211 ground-truthed by observations of rock exposures in modern and uplifted cliffs.
212 According to the referential values of electrical resistivity of rock formations presented
213 in selected literature (Stenzel and Szymanko 1973, Telford et al. 1990, Kearey et al.
214 2002, Milsom 2003, Kneisel and Hauck 2008, Reynolds 2011) it was assumed that
215 high values of apparent resistivity ($\rho \geq 1 \text{ k}\Omega \text{ m}$) are typical for cryotic formations.
216 Figure 3 shows that value ranges for particular rock formations are wide and often
217 overlap one another. Therefore the final result of our interpretation was influenced by
218 hard to separate factors i.a. structure and texture of investigated rocks, their
219 mineralogical composition, thickness, water content or salinity.

220

221 Fig. 3. Range of resistivity detected in various environments, based on: Stenzel and
 222 Szymanko (1973), Telford et al. (1990), Kearey et al. (2002), Milsom (2003), Kneisel and
 223 Hauck (2008), Reynolds (2011).

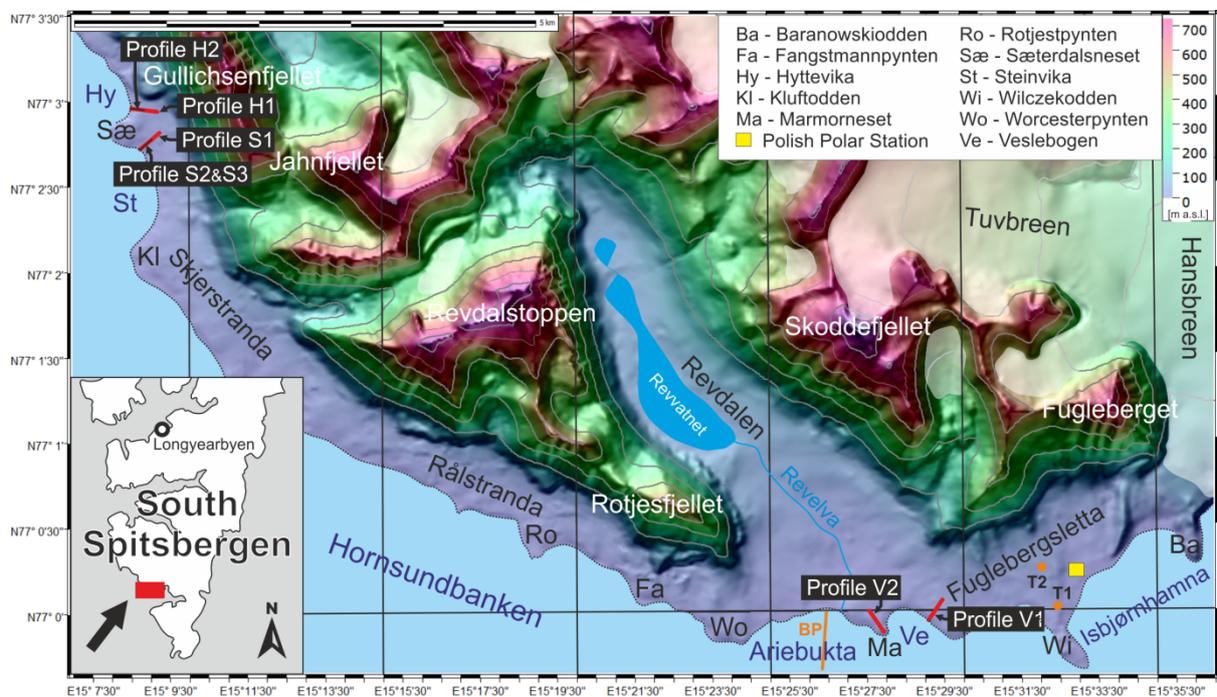

224

225 **Study area**

226 The study is located in the northern coast of Hornsund in south-western Spitsbergen
 227 (Fig.4). The coastal zone is generally low and the present-day cliffs are abraded in
 228 strandflat surface elevated by 8–25 m a.s.l. Majority of rocky cliffs are less than 10 m
 229 high. Numerous skerry islands and rocky stacks are scattered along the coast,
 230 indicating the extent of shore platform up to ca. 300 m seawards. Small embayments
 231 and coves are filled with gravel-dominated beaches which are often terminated by
 232 low cliffs. Coastal landscape is dominated by uplifted marine terraces and palaeo-
 233 skerries and rocky cliffs. Staircase of ca. 15 uplifted marine terraces reaching up to
 234 220 m a.s.l. has been identified in the area (Jahn 1959, 1968, Chmal 1987,
 235 Karczewski et al. 1990, Migoń 1997, Zwoliński et al. 2013).

236 The north-western Hornsund region is underlain by Precambrian basement rocks,
 237 which are a part of lower and middle Hecla Hoek succession, covered by Cambrian
 238 and Ordovician sedimentary successions (Czerny et al. 1992). Present-day cliffs,

239 stacks, skerries and shore platforms are formed in quartzites, schists, paragneisses,
 240 marbles and amphibolites. Due to a diverse geological structure of the coastline, the
 241 measuring points were deliberately located on fragments with lithologically
 242 homogenous bedrock. The ERT Profiles 'S' and 'H' by Sæterdalsneset (Fig. 4) were
 243 created in the area made of white and green quartzites belonging to the
 244 Gulliksenfjellet Formation, while the ERT profiles 'V' made by Veslebogen were in the
 245 reach of the Ariekammen Formation; yellow and white calcite marbles (Profile V1)
 246 and garnet-calcite-mica schists (Profile V2).

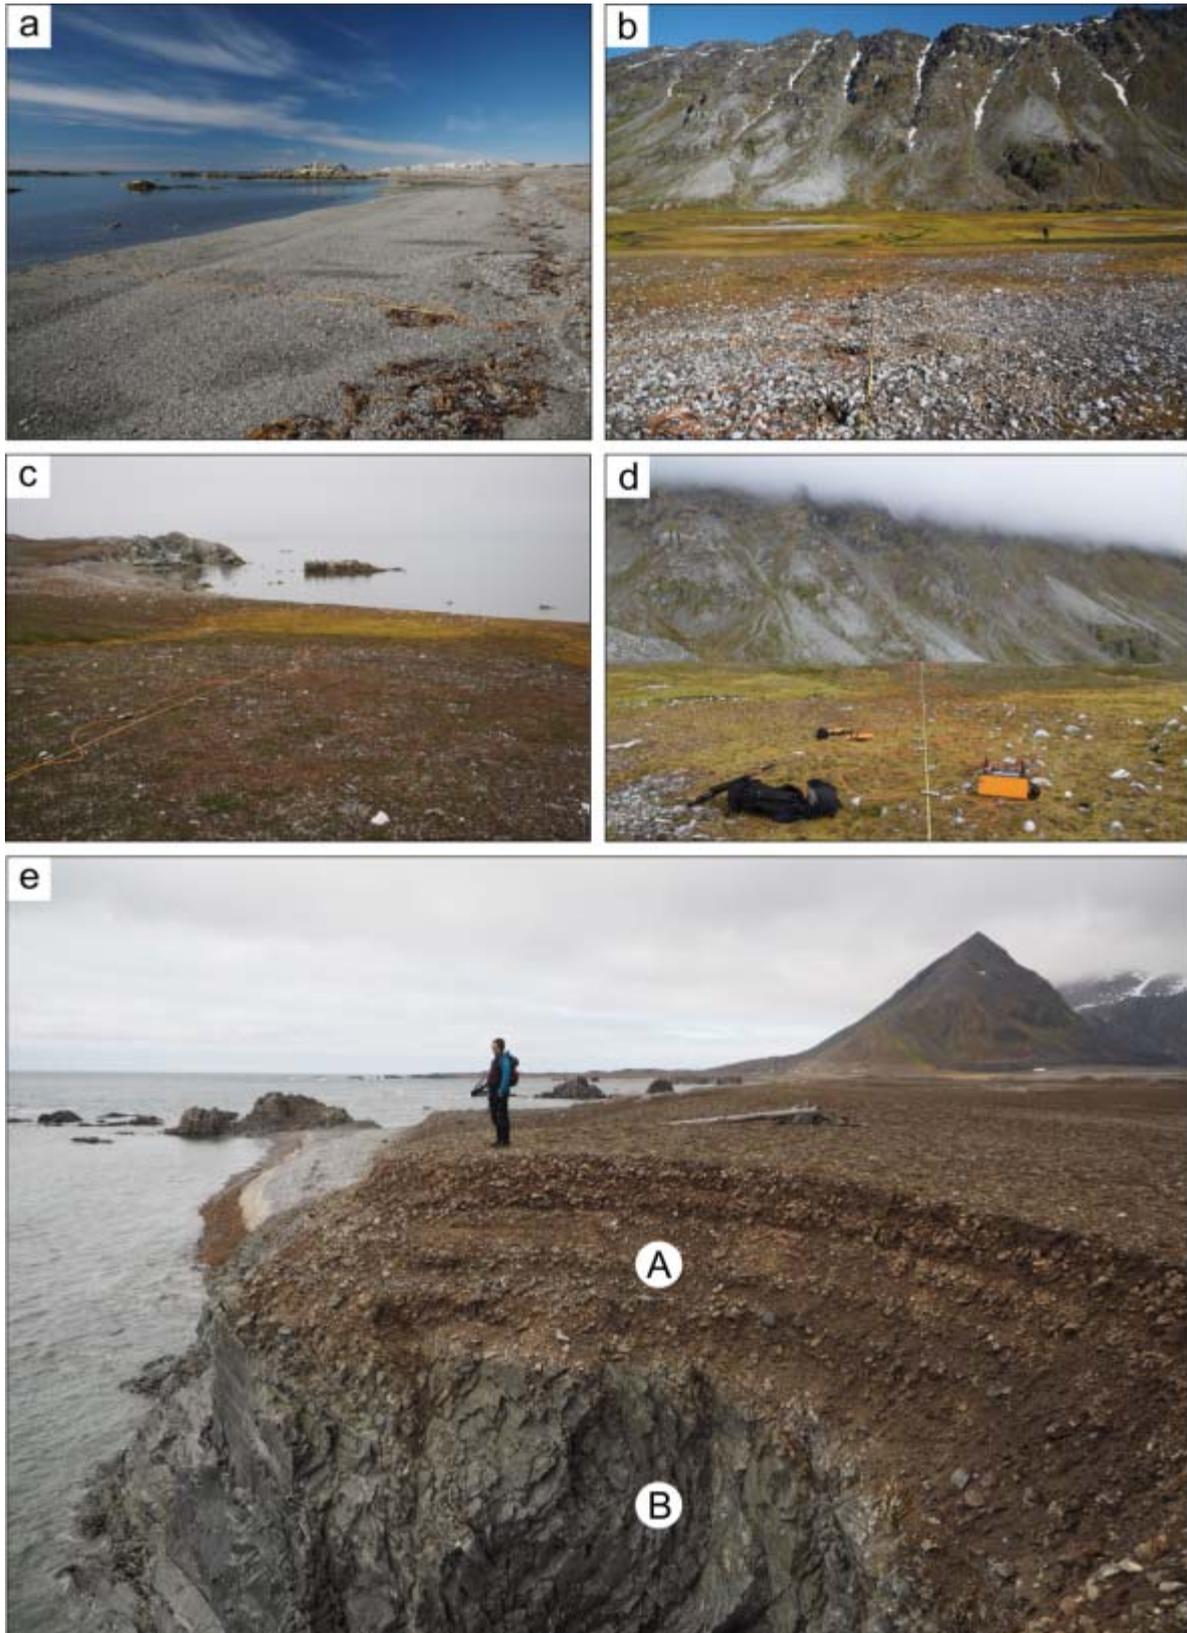

247
 248 Fig. 4. Study area near Hornsund with location of electrical imaging profiling (Profiles H, S,
 249 V); BP – bathymetric profile by Swerpel (1982) showed on fig. 7, T1 – 1.6 m depth bore hole
 250 with ground temperature measurements done in 1957–1960 (Baranowski 1968), T2 – 3 m
 251 depth bore hole with ground temperature measurements done in 1986–1967 (Baranowski
 252 1968). DEM image based on Norsk Polar Institute data.

253
 254 Solid rocks of the base in the measuring points are covered with a marine sediment
 255 which are well grinded gravels and fine-grained material (Fig. 5a–d). The surface
 256 sediment cover has got a relatively little thickness, reaching maximum 2–2.5 m,

257 which may be observed by the sea cliff bluffs (Fig. 5d). Near the paleoskerries
258 diversifying the surfaces of raised marine terraces, the thickness of loose formations
259 decreases. The initial pedogenesis has already transformed surface of older marine
260 terraces (Kabała and Zapart 2009, Szymański *et al.* 2013, Migąła *et al.* 2014).

261 Climatic conditions in northern Hornsund are common for the western Spitsbergen.
262 The mean annual air temperature for the period of 1979–2012 was -4.1°C , with the
263 minimum in January (-11.3°C) and maximum in July (4.4°C) (Kępski *et al.* 2013).
264 The trend of annual air temperature rise for the period 1979–2009 is $+0.096 (\pm$
265 $0.021)^{\circ}\text{C}/\text{year}$ (Marsz 2013a). The air humidity in the area of Hornsund is significant
266 and its average is 79.4%, increasing during the summer months (Marsz 2013b). The
267 mean measured total precipitation for the investigated period was 434.4 mm a year,
268 with its maximum in August (64.4 mm) (Łupikasza 2013). On average, the ground
269 surface in Hornsund is covered with snow for 244 days a year (Niedźwiedź and
270 Styszyńska 2013).

271

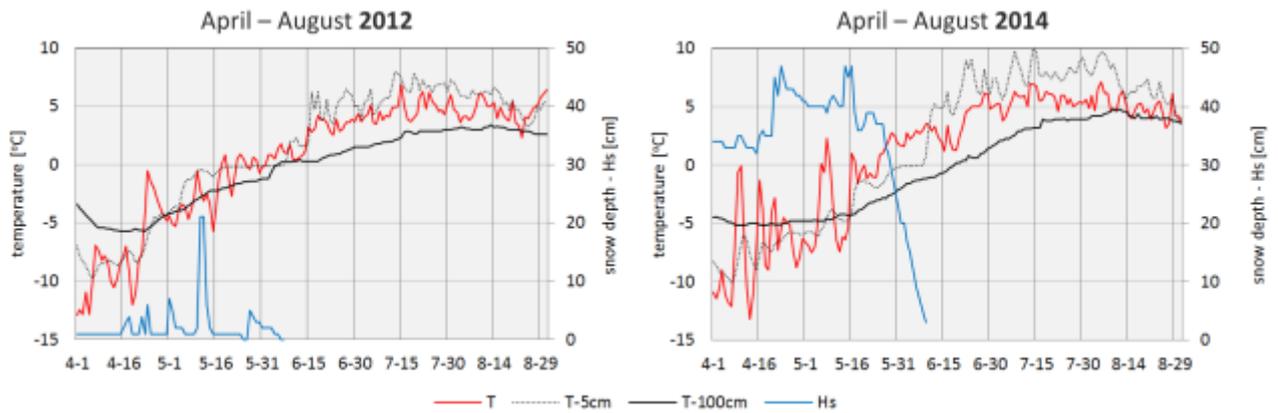

272

273 Fig. 5. Study sites selected for ERT measurements (photos by M. Kasprzak): a,b) seaward
 274 and landward views at ERT profiles in Steinvika – Profiles S1–S3; c,d) seaward and
 275 landward views at ERT profiles in Hyttevika – Profiles H1, H2; e) Headland in Veslebogen
 276 (Profiles V1, V2), A – solid rock, B – marine deposits cover.

277

278 The thickness of active layer is controlled by topography and bedrock lithology. Mean
279 thickness of active layer is 1–1.15 m (Baranowski 1968, Jahn 1982, Grześ 1985,
280 Migala 1994). On the raised marine terraces active layer developing in saturated
281 clays covered by tundra reaches up to 0.7 m whereas in shallow humid depressions
282 filled with mud active layer thaws up to 0.9 m. Active layer depth under large
283 polygons and stone rings is 1.4 m. It thaws even deeper in uplifted beaches
284 composed of mixed sand-gravel deposits 1.38–2.21 m (Migala 1994) and 2.30 m
285 (Chmal et al. 1988). The thinnest active layer depths are observed in areas covered
286 by peat (on average 0.4 m, Jahn 1982). The thawing of active layer is accelerated
287 due to increasing high maximum temperatures. The maximum air temperature
288 measured in the study area at the ground surface covered by tundra was 22°C
289 (Migala *et al.* 2014). The measurements carried out other parts of Svalbard showed
290 that extreme near-surface temperatures may cause thermal responses even up to 15
291 m deep (Isaksen et al. 2007). **Figure 6** summarises the meteorological conditions
292 during spring and summer periods before the measurements.

293 Changes of thermal conditions of water masses at the mouth of Hornsund are
294 associated with the mixing of cold Arctic water mass carried by the East Spitsbergen
295 Current and warm Atlantic water mass carried by the West Spitsbergen Current
296 (Majewski et al. 2009). There is only few data on physical and chemical properties of
297 coastal waters in the study area.

298

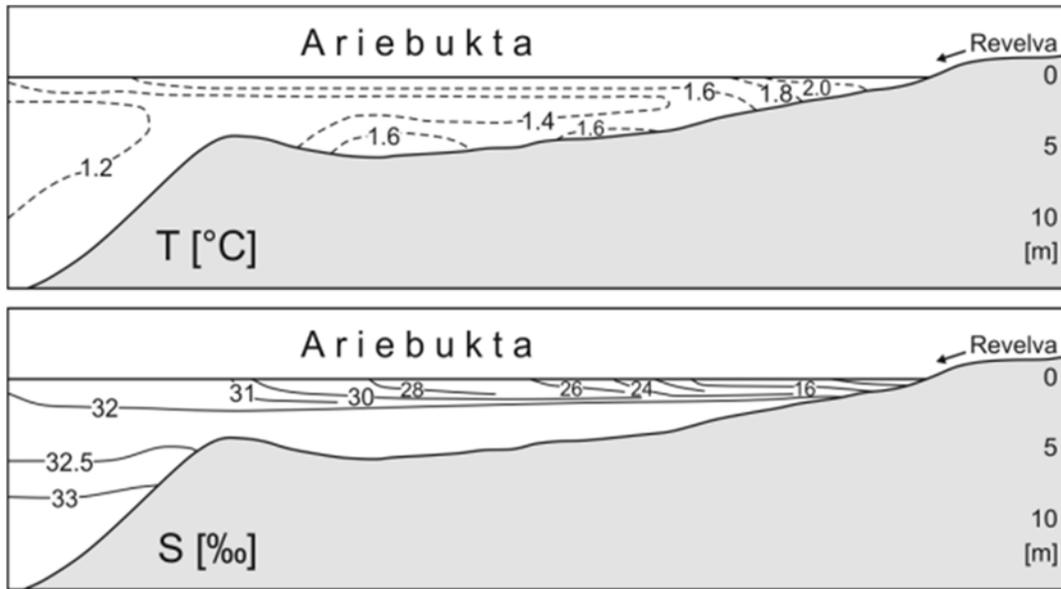

299 Fig. 6. Meteorological conditions before ERT measurements carried out in summers 2012
 300 and 2014 in Hornsund: T – mean daily air temperature, T–5cm – temperature of ground at
 301 0.05 m under the surface, T–100cm – temperature of ground 1 m under surface, H_s – snow
 302 depth. Source: Hornsund GLACIO-TOPOCLIM Database: <http://www.glacio-topoclim.org>
 303 (retrieved on 24th November 2014).

304

305 The bathymetric profile with measurements of water temperature and salinity was
 306 made in the summer 1975 for Ariebukta by Swerpel (1982, 1985). His study showed
 307 that the water temperature at the surface decreased from the coast towards the sea
 308 (Fig.7). At depths below 5 m a cold current was observed (water temperature below
 309 1.4°C). In the test section salinity also grew with distance from the shore and with
 310 depth. It was the highest 33.46 ‰ at the depth of 10 m on the slope of shore platform
 311 and the lowest 14.27 ‰ by the shore of the bay. Changes of water properties were
 312 also influenced by the flux of freshwater from the Revelva, which flows into Ariebukta.
 313 At the time of measurement the mean salinity of coastal waters in Ariebukta (northern
 314 Hornsund) was 31.64‰ (Swerpel 1982). More recent study on Hornsund seawater
 315 properties was conducted by Zajączkowski et al. (2010). In the summers of 1999,
 316 2000 and 2002, at the entrance of the Hornsund the near-bottom temperature (at 151
 317 m depth) was 1.27–2.02 ° C and a near-bottom salinity in the summer of 2002 was
 318 34.73 ‰. The maximum sea ice thickness in inner part of Hornsund varies is ca. 1.5
 319 m (Gerland and Hall 2006). With favourable weather conditions, a vast coastal ice

320 and icefoot is formed, which protects the shore from storm waves over autumn and
 321 winter months (Rodzik and Wiktorowicz 1995). The entrance to the fjord is normally
 322 ice free by the beginning of June (Urbański et al. 1980, Węśławski et al. 1988).

 326 1 km long) in summer of 1975 (20th August), local sea water conditions are modified by
 327 Revelva's mouth and fresh waters inflow (after Swerpel 1982, modified)

328

329 Results and interpretation

330 Field investigations resulted in obtaining several inversion results showing apparent
 331 resistivity of the ground in seven measurement profiles (3 profiles in Steinvika, 2
 332 profiles in Hyttevika, 2 profiles in Veslebogen). Table 1 summarises basic data on the
 333 measurement profiles and the results of ERT measurements. The received maximum
 334 apparent resistivity values are relatively high and are ρ_{max} 7 774.1–17 868.1 Ω m
 335 (see Fig. 3 for comparison). The median values equalled ρ_{me} 497.1–3809.0 Ω m.
 336 Large standard deviations were also registered ρ_{SD} 1093.1–2941.7 Ω m, indicating a
 337 diversity of the examined rocks in terms of geoelectrical properties. 315 m long
 338 profiles based on 5 m electrode spacing allowed to penetrate the ground to the depth

339 of ca. 50 m. Shorter profiles (71 m, 142.5 m) with the electrode spacing 1 and 1.5 m
 340 respectively reached ca.. 8 and 11–17 m depths.

341 Tab. 1. Summary of ERT measurements and inversion results. SD – standard deviation,
 342 RMS error – root-mean-square deviation (differences between value predicted by a model
 343 and the values measured).

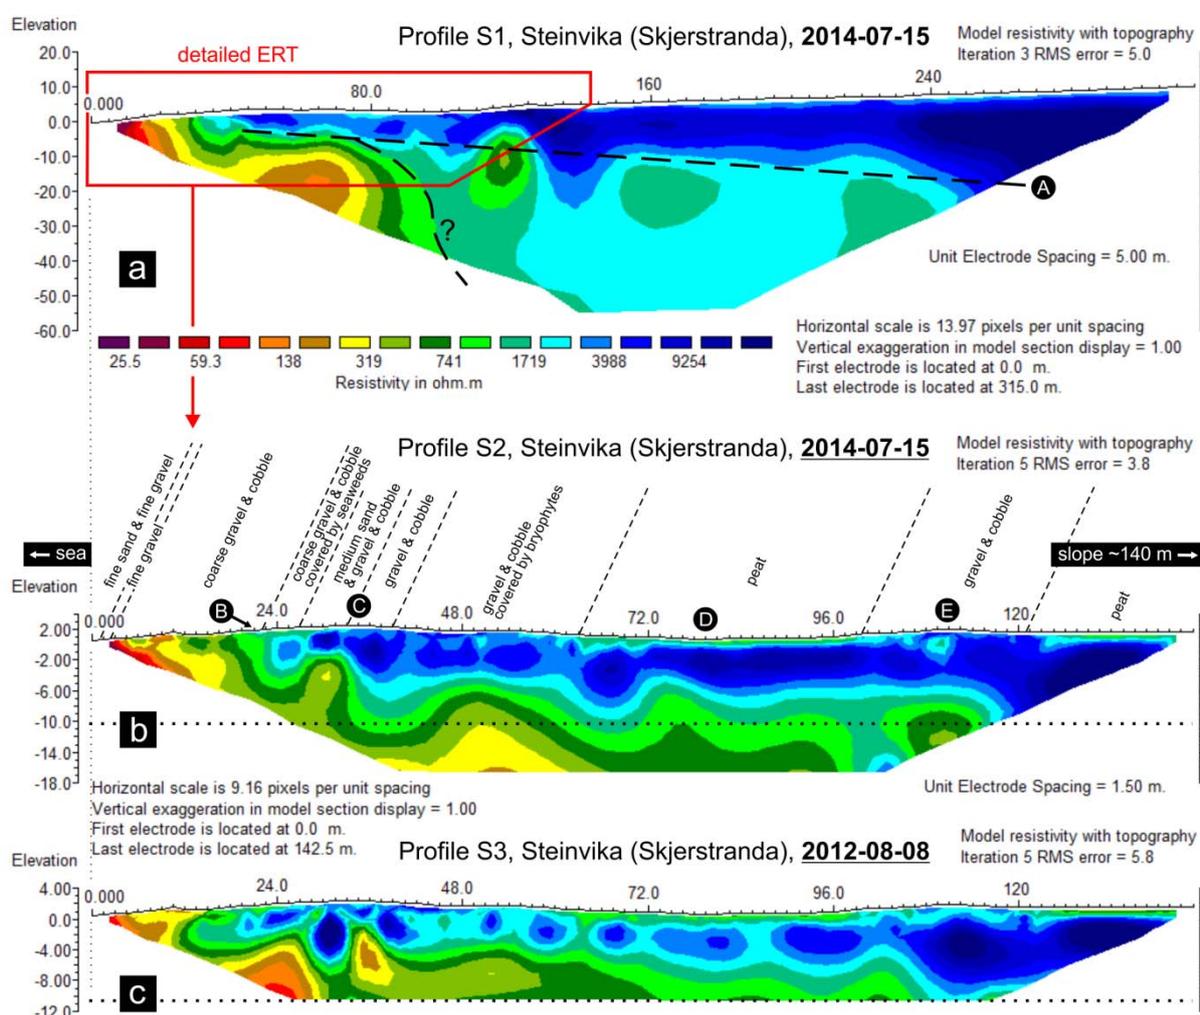

No	Locality	Date	Profile length [m]	Electrode spacing [m]	Electrode array	Apparent resistivity [Ohm m]				Inversion

344

345 **Steinvika.** The Steinvika case study is presented in a first place because in our
 346 opinion the results obtained from ERT measurements present a model situation of
 347 the development of ‘reverse’ active layer in coastal permafrost. The general state of
 348 frozen ground conditions were examined in the ERT Profile S1 extending from the
 349 coastline for 315 m inland to the foot of the massif Gullichsenfjellet (fig. 8a). The
 350 profile led from the shoreline through three marine terraces covered with well-
 351 preserved beach ridges. Except for the modern coastal zone and crests of beach
 352 ridges, the profile surface was covered with tundra. Majority of hollows and flat
 353 surfaces located ca. 60 m from the shoreline were vegetated by wet mires.

354 The inversion results showed that ground resistivity in close vicinity of the sea is low,
 355 which excludes the existence of permafrost, including submarine permafrost. The
 356 highest resistivity $\rho > 2$ k Ω m characterised the subsurface ground layer and started
 357 at ca. 20 m from the coastline, continuing inland. The tomogram points with the
 358 highest resistivity formed a wedge with thickness decreasing seawards.

359 Approximately 100 m off the shoreline the body of the highest resistivity had a mean
 360 thickness of up to 10 m, and up to 20 m ca. 220 m away from the sea. The surface
 361 part of the body had lower resistivity and was associated with thawed active layer.
 362 The lower boundary of the high-resistivity field had an irregular shape and was limited
 363 by points (areas) of low resistivity. The smallest resistivity was found in the intertidal
 364 zone, exposed during the low tide. The zone of low resistivity developed further
 365 inland under the frozen layer (under permafrost).

366
 367 Fig. 8. a) Inversion results of electrical imaging of Profile S1 in Steinvika; b,c) detailed ERT
 368 image of coastal zone repeated in 2 years time interval (b and c). Legend: A –boundaries
 369 between permafrost and non-frozen ground below (permafrost base), B – current storm ridge
 370 and line of drift wood, C – older storm ridge, D – the lowest point between older storm ridges,
 371 E – old storm ridge. The dotted line indicates max depth of Profile 3. The colour scale was
 372 unified for all resistivity models.

373

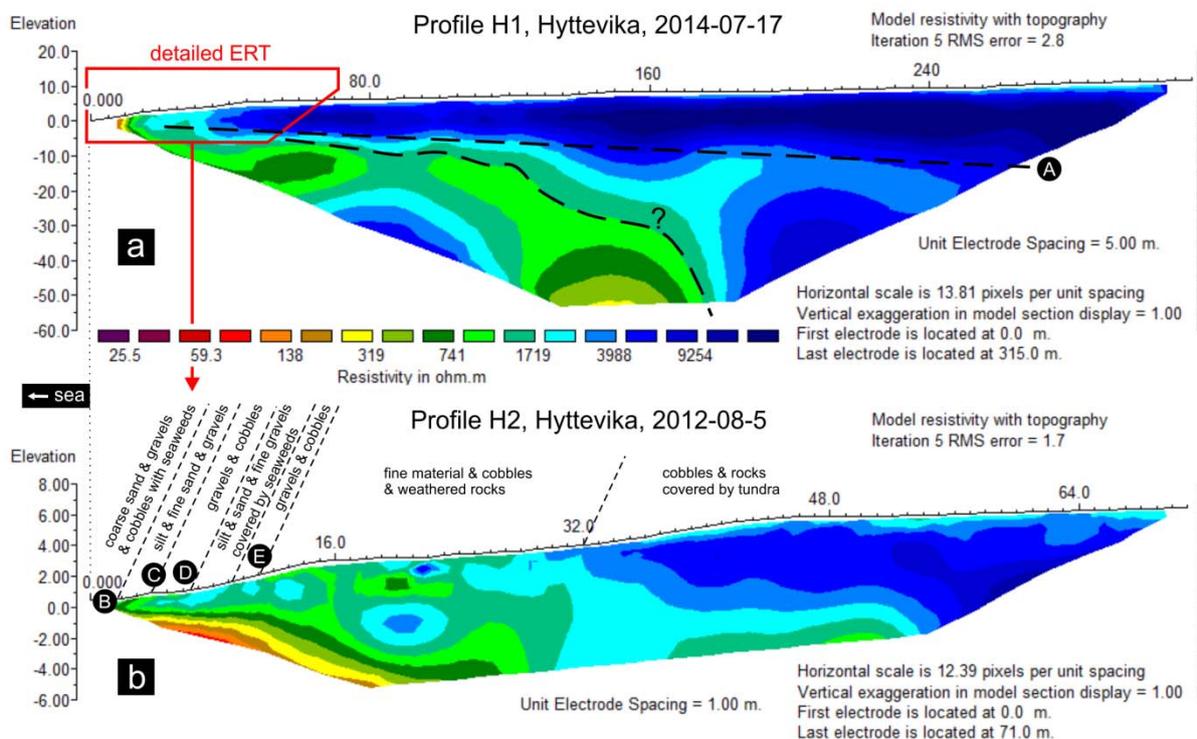

374 First ERT measurements in Stenivika were carried out in August 2012 when 142.5 m
375 long profile (Profile S3) with 1.5 m electrode spacing was made (fig. 8c). In July 2014
376 the ERT measurements were repeated following the same profile line and electrode
377 spacing, but using a larger number of cables (fig. 8b), thus the inversion results at the
378 same spacing between the electrodes vary in the probing depths. Smaller electrode
379 spacing enabled obtaining a higher resolution image and helped in precise detection
380 of active layer that formed a clearly visible layer from ca. 60 m of the profile.

381 The permafrost represented by points (fields) with the highest resistivity was not
382 homogenous. In terms of geoelectrical features the fragmentation of the permafrost
383 layer was particularly visible on Profile S3 and generally increased seawards. It is
384 important to note that in tomogram developed from Profile S3 (August 2012) a zone
385 of particularly high resistivity developed under the modern storm ridge (ca. 34 m of
386 the profile), which was not observed 2 years later (profile S2). Comparison of the two
387 detailed measurements enabled to detect temporal change in geoelectrical features
388 of the permafrost layer, changes in the active layer thickness and changes of
389 permafrost base with the highest resistivity.

390 **Hyttevika.** In contrast to Steinivika site the ERT profile (Profile H1) carried out across
391 Hyttevika coastal zone (fig. 9a) was characterised by steeper slope. The inversion
392 results allowed to distinguish the body with the highest resistivity reaching the coastal
393 zone and underlying zone of lower resistivity developing inland from the sea. A
394 narrow (ca. 5 m wide) coastal strip by the shoreline exposed during a low tide was
395 characterised by low resistivity excluding presence of permafrost. Until the 180 m of

396 the ERT profile the thickness of the body with the highest resistivity did not exceed 15
 397 m.

398 The interpretation of the lower parts of the tomogram was more difficult. This is due
 399 to the interpolation effects caused by extremely different values of single points
 400 occurring at the edges of the tomogram. The system of geoelectrical features in the
 401 centre part of the profile suggested, however, the existence of a boundary between
 402 thawed and frozen parts of the coastal zone at 180 m of the profile.

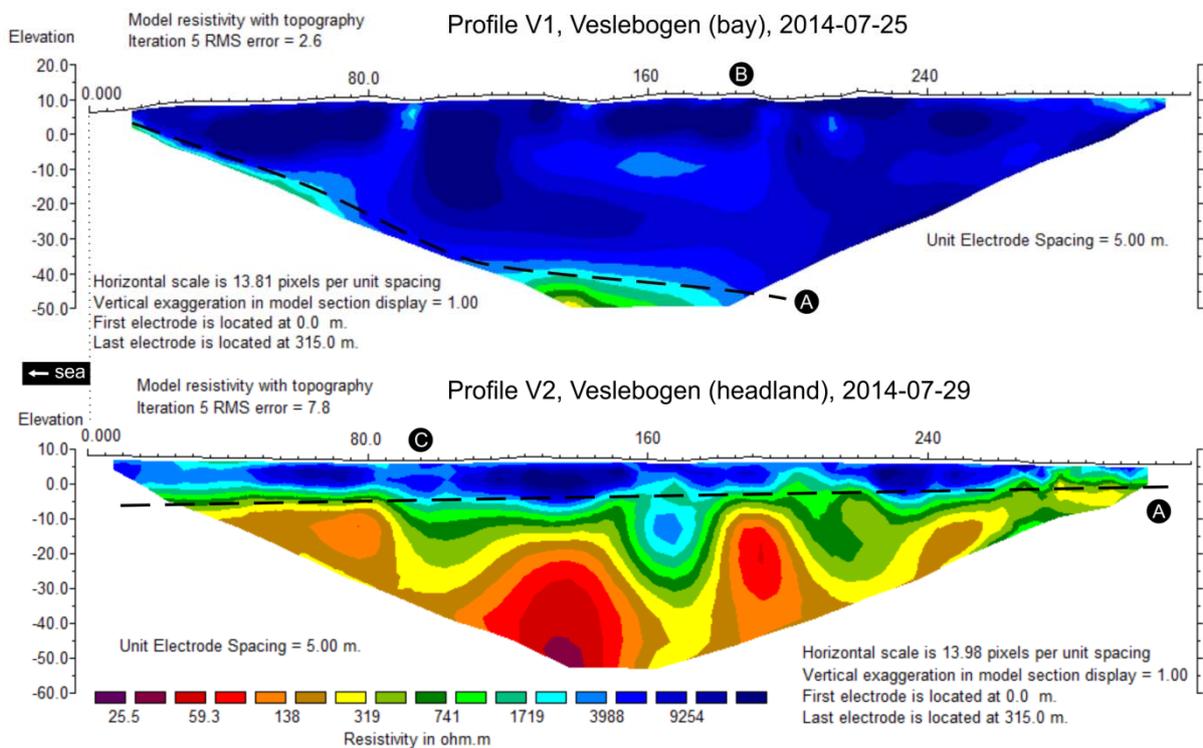

403
 404 Fig. 9. a) Inversion results of electrical imaging in Hyttevika; b) more detailed ERT image of
 405 coastal zone. Legend: A – boundaries between permafrost and non-frozen ground below
 406 (permafrost base),. B – berm, C – storm ridge, D – swale, E – older storm ridge (abraded
 407 slope). The colour scale was unified for all resistivity models.

408
 409 In Profile H2, carried out in August 2012 (Fig. 9b), the inland penetration of a wedge
 410 of high resistivity was clearly visible. Approximately 32 metres from the start of the
 411 profile (low-water mark) and before reaching the area covered by uplifted marine
 412 terrace (6–8 m a.s.l.), a noticeable resistivity change in the upper part of ground was

413 detected. Almost on the entire length of the profile the formation of active layer with
 414 lower resistivity than in deeper parts of the profile was observed. The active layer
 415 thickness increased seaward from the section of the profile covered with uplifted
 416 marine landforms (terraces with beach ridges).

417 **Veslebogen.** The ERT measurements in Veslebogen indicated large differences
 418 between the inversion results of the profiles led across coastal zone in the sheltered
 419 embayment (Profile V1, Fig. 10 a) and in an exposed and relatively narrow (ca. 150 m
 420 wide) headland (Profile V2, Fig. 10 b). The low resistivity values interpreted as
 421 unfrozen rock were detected only along the edges of tomogram from seaside section
 422 of Profile 6 . In this place the electrical resistivity method with the available quantity of
 423 terminals for electrodes reached the limits of its usefulness. Coastal zone in Profile
 424 V1 contained frozen body of dozen of meters thick in the area up to 70 m from the
 425 shoreline, and up to 40 meters thick from 180 m inland.

426

427 Fig. 10 Inversion results of electrical imaging in Veslebogen :a) sheltered embayment, b)
428 headland exposed to the operation of waves and tides. Legend: A – presumed boundary
429 between permafrost and non-frozen ground below (permafrost base), B – solid rocks
430 (paleoskiers), C – single frost crack. The colour scale was unified for all resistivity models.

431

432 The inversion results from the headland (Profile V2) were drastically different than in
433 the embayment. High resistivity $\rho > 1 \text{ k}\Omega \text{ m}$ was characteristic only for the upper part
434 of the profile, to the depth of 5–10 m, and were interpreted as a permafrost. The
435 lithological boundary at ca. 2.5–3 m depth between marine gravels covering the top
436 of headland and solid rock (Fig. 5d) was not distinguishable in terms of electrical
437 resistivity. The lower parts of the profile showed a notably lower electrical resistivity
438 ($\rho < 300 \Omega \text{ m}$) and may be interpreted as unfrozen solid rock. Such a situation may
439 be associated with the exposure of the headland to the operation of waves and tides
440 affecting physical and chemical properties of the rock.

441

442 **Discussion**

443 The ERT measurements and interpretation of the inversion models require few
444 comments on the possible measuring and interpretation errors. Due to the time limit
445 and safety reasons (wandering polar bears, damage of measuring cables by polar
446 foxes and reindeers) the measurements were conducted only once and using only
447 one method. The chosen measurement method (Wenner-Schlumberger) is relatively
448 universal one in imaging horizontal and vertical structures, but could not provide
449 deeper penetration, as in the Dipole-Dipole electrode array (Reynolds 2011). The
450 received inversion models, though used to deduce on the ground thermal state,
451 relate directly not to the temperature but apparent resistivity. In addition, their
452 graphical representation is a result of interpolation, which largely depend on the

453 distribution of points with extreme values. Therefore our interpretation of the inversion
454 results, not supported with ground temperature monitoring, was based on the
455 geoelectrical characteristics of rocks known from the literature (see Fig. 3). In our
456 study we have also considered the results of previous works comparing the ground
457 temperature data with the ERT data (e.g. Hayley et al. 2007, Overduin et al. 2012,
458 You et al. 2013), with particular attention on reports from surveys across coastal and
459 nearshore zones (e.g. Sellmann et al. 1988). Nevertheless, information from literature
460 is not consistent, and difficulties in establishing a clear range of resistivity typical for
461 the permafrost, result from many factors affecting the geoelectrical properties of the
462 ground. For this reason, marking of the boundary between frozen and unfrozen
463 grounds shown in Figures 8–10 was arbitrary. In case of Profiles S1 and H1 two
464 alternative variants of a boundary have been suggested.

465 We took for granted that the ground electrical resistivity strongly depends on its
466 thermal state (Rein et al. 2004, Halley et al. 2007). Field observations carried out by
467 MacKay (1969) showed that the apparent resistivity of the rock mass increases
468 together with temperature fall. MacKay's (1969) study also pointed to large resistivity
469 differences (2–3 orders of magnitude) characterising surface sediments of Mackenzie
470 River Delta. The resistivity of frozen gravel with sand was determined at 20–22 k Ω m,
471 while unfrozen sand and gravel had resistivity at 0.015–0.080 k Ω m. The connections
472 of resistivity changes depending on the ground thermal state were also proved by the
473 Antarctic study by McGinnis et al. (1973) carried out over a wide range of negative .
474 The authors demonstrated that the value of $\rho = 1$ k Ω m does not have to indicate
475 rock freezing. McGinnis et al. (1973) paid attention on the issue of ground porosity
476 and found out that at 0°C all saturated porous soils and rocks have resistivity lower
477 than 700, whereas small nonporous rocks may have resistivity as great as 5 000.

478 Similar measurements carried out in 20–50 m deep boreholes in Qumahe in the east
479 of the Tibetan Plateau indicated that frozen formations may have much lower
480 resistivity, about $\rho \approx 180 \Omega \text{ m}$ (You et al. 2013). However, other permafrost resistivity
481 measurements show quite contrasting situation. Larin et al. (1978) found out that in
482 the Arctic islands and along (Siberian) Arctic coasts Quaternary sediments have
483 resistivity 0.8–80 k $\Omega \text{ m}$ and pre-Quaternary rocks 1–3 k $\Omega \text{ m}$, whereas subpermafrost
484 and intrapermafrost horizons of the fresh and slightly saline water are characterised
485 by resistivity of about 0.1 k $\Omega \text{ m}$. Similar measurements of electrical properties of
486 frozen silt made by Arcone and Delaney (1988) showed that the ground resistivity
487 values above $\rho > 1 \text{ k}\Omega \text{ m}$ generally indicate ice content higher than 40%.

488 The interpretation of received inversion results is facilitated by the fact that the
489 subject of the research is ground with relatively high temperature, so called "warm
490 permafrost" (Gregersen and Eidsmoen 1988). In Spitsbergen, the borehole
491 temperature measurements demonstrated that at 30 m depths the permafrost
492 temperatures are -3.0°C and -2.4°C at the mineralization of aquifers 34–44 $\text{g}\cdot\text{l}^{-1}$
493 (Oberman and Kakunov 1978). Similar calculations supported by the ground thermal
494 measurements in Longyearbyen and Svea allowed Gregory and Eidsmoen (1988) to
495 infer that along the southern and western coasts of Spitsbergen the mean ground
496 temperature inside the in the shore is $1\text{--}2^\circ\text{C}$ below zero, while further inland the
497 surface temperature is above zero and permafrost conditions are present at few
498 metres depths.

499 It is also difficult to clearly distinguish the differences in resistivity caused by the
500 thermal state from the differences arising from the salinity of the coastal sediments.
501 According to Gregersen et al. (1983) salty soils remain unfrozen even at -2 to -3°C .
502 During the investigations of the phase composition of the water and structural

503 properties of saline soils Tsyтович et al. (1978) noticed a shift of the phase transition
504 from about -0.4 to -1.6°C (frozen) and -0.6 to -3.5°C (thawed) for soils with low
505 salinity and from -1.2 to -21.8°C (frozen) and -4.9 to -41.0°C (thawed) for soils with
506 high salinity.

507 Very low resistivity values observed during this study in the seaward part of the
508 coastal zone (even $\rho < 50 \Omega \text{ m}$) indicate that this zone is unfrozen, at least in the
509 subsurface layer of the intertidal zone. The lack of submarine permafrost in the
510 coastal zone contradicts the first calculations of Werenskiold (1922), and is different
511 from the conditions of the coastal zone in other parts of the Arctic, e.g. the Kara Sea
512 (Rekant et al. 2005) or the Beaufort Sea (Hunter et al., 1988, Overduin et al. 2012).
513 However, it is coherent with the views on the state of Svalbard coastal zone
514 presented by Soloviev (1988) who stated that the seabed along the eastern coast of
515 the Svalbard is devoid of permafrost. According to Soloviev (1988) the seabed along
516 northern Spitsbergen and Franz Josef Land coasts remains mainly unfrozen, and
517 seasonal freezing of sediments deposited at the bottom of the coastal waters starts
518 around the southern tip of Novaya Zemlya ($\phi 70^{\circ}\text{N}$). The zone of the permanently
519 frozen seabed extends approximately from the central part of Novaya Zemlya to the
520 north-east (in the direction of Franz Josef Land).

521 Our results suggests that the thawed zone continues from the sea towards the land
522 and continues under the permafrost body. The geometrical arrangement between
523 bodies with different resistivity resembles the shape of the contact zone between
524 seawater and freshwaters with different physical and chemical features observed on
525 carbonate islands and coasts of Bahamas (Myroie and Carew 2000, 2003). In the
526 aforementioned example, in less mineralised freshwater karstic voids have
527 developed. In case of our study site the permafrost body would correspond to the

528 shape of freshwater lens which base was shaped in the zone of halocline (vertical
529 salinity gradient within a body of water, where the fresh-water to salt-water boundary
530 is sharp or in the mixing zone). The inversion results suggest that permafrost
531 thickness in the coastal zone exposed to operation of waves and tides is very limited.
532 A body of resistivity $\rho > 1 \text{ k}\Omega \text{ m}$ at the distance of 100 m from the shoreline is thinner
533 than 10 m (except Profile V1 in sheltered embayment). Similar thawing of the ground
534 under permafrost was previously observed in more inland areas and linked with the
535 underground discharge of meltwaters from glaciers (e.g. Haldorsen et al. 1996, Booij
536 et al. 1998, Haldorsen et al. 2010). However, the spatial variation of permafrost
537 thickness was not the subject of those investigations, and in our opinion the
538 established patterns of the water discharge under the permafrost were too simplified.
539 For example, Haldorsen et al. (1996) showed permafrost in a schematic model of the
540 subpermafrost groundwater system as a body of practically constant thickness of ca.
541 100 m across the entire coastal zone and ending in the seabed zone. Therefore, their
542 general model contradicts our interpretation and do not fit into a well-known pattern,
543 presented by Lachenbruch (1968) or Gold and Lachenbruch (1973), showing the
544 effect of surface features on the distribution of permafrost in the continuous
545 permafrost zone. It is noteworthy that smaller thickness of coastal permafrost was
546 indicated by earlier investigations by Harada and Yoshikawa (1996, 1988). The
547 electrical soundings with the Wenner electrode configuration in the Adventdalen delta
548 (2 m a.s.l.) allowed them to define the permafrost thickness of 31.7 m.

549 To our knowledge the influence of the shape of the coast on permafrost thickness
550 has not been studied. Our results show that on the contrary to sheltered embayments
551 the operation of wave and tides on exposed parts of the coastal zone (headlands)
552 results in a weaker development of permafrost. Perhaps this relationship was taken

553 into account by Gregersen and Eidsmoen (1988), who included "shoreline
554 topography" in the list of local factors controlling coastal permafrost properties.
555 Variations in permafrost thawing conditions was previously studied along the shelf of
556 Canadian Beaufort Sea. Hunter et al. (1988) showed that the summertime
557 temperature configuration indicated a thin thaw zone above 0°C along the entire shelf
558 section out to 800 m offshore. In the nearshore zone, at water depths less than 1 m,
559 the thaw zone was less than 0.5 m thick. In deeper waters (>2 m), the thaw zone
560 increased to 8 m thickness.

561 The resistivity models received from our study show that coastal permafrost is not
562 homogenous. As presented on each of the tomograms, the permafrost body with the
563 highest resistivity in the subsurface section of the ground is highly differentiated in
564 terms of resistivity. This is particularly evident in profiles characterised by higher
565 resolution (Profiles S2, S3, H2). The highest resistivities $\rho > 2 \text{ k}\Omega \text{ m}$ were marked just
566 10–20 meters from the shore. In Profile S3, the existence of several 'islands' of high
567 resistivities along the distance of 100 m to the sea actually reminds discontinuous
568 permafrost. However, we agree that without ground temperature measurements,
569 such a conclusion may not be clearly verified, especially when we take into account
570 that according to Brown et al. (1997) Svalbard lays in a zone of continuous
571 permafrost (extent of 90–100%).

572 In each profile the active layer was characterised with reduced resistivity. Due to the
573 limits of the ERT method (no registration of surface points) and applied electrode
574 spacing, only the bottom part of the active layer was registered even in the profiles
575 with higher resolution. In general active layer thawing from the ground was weaker
576 under beach ridges and stronger in depressions filed with humid mires. Development
577 of thicker active layer in Profile 3 than in Profile S2 may be associated with the timing

578 of measurement. Profile S3 was carried out one month later than Profile S2 (August
579 2012 – July 2014). Second factor that may led to stronger thawing of active layer in
580 2012 were meteorological conditions during the spring period (see Fig. 6). In contrast
581 to the spring 2014 the spring 2012 was devoid of thick snow cover which has a
582 strong influence on active layer thawing (Harris et al. 2009). Although in 2012 the
583 ground temperatures at 1m depth rose above 0°C earlier than in 2014 (6th of June
584 2012 – 19th of June 2014) in August 2014 the ground temperature was higher than in
585 August 2012. On the 13th of August 2012 the ground temperature at 1m was 3.4°C,
586 while on the 9th of August 2014 the temperature reached 4.8°C. Overall, the ERT
587 image of the thawed ground generally confirmed the earlier near-surface
588 observations on the state of permafrost in Hornsund region (Baranowski 1968, Jahn
589 1982, Grześ 1985, Chmal et al. 1988, Migala 1994, Dolnicki et al. 2013).

590 The repeated ERT measurements in 2012 and 2014 (Profiles S2 and S3)
591 documented also resistivity changes in deeper ground sections. We have associated
592 those changes with the impact of seawater temperature and salinity. Similar
593 conclusion was presented by Molochushkin (1978) who discovered that even
594 relatively cold (mean annual temperature 0.2–0.3°C) and slightly salty (20‰)
595 seawater in the Laptev Sea accelerated the degradation of coastal permafrost.
596 Several authors reported development of active layer in seabed sediments deposited
597 along the coast of the Beaufort Sea (Mackay 1972, Hunter et al. 1988). The seasonal
598 changes in the thermal state of submarine permafrost were associated with the
599 impact of fluxes of warm freshwater from the Mackenzie River.

600 Our results confirmed that heat waves found in the winter 1986/1987 at the base of
601 ground temperature monitoring boreholes may be caused by the influence of
602 relatively warm and salty seawater on deeper ground sections. This study

603 supplemented the observations by Baranowski (1968) by showing that the inland
604 heat wave advancing the sea may affect the state of permafrost in solid rock. The
605 dominant role on the variation in the resistivity values was played by a thermal factor.
606 For instance, in Profile V2 strong freezing of geological formations covered up clear
607 lithological boundaries in the received image. The obtained tomograms enabled
608 analysis of spatial distribution of permafrost which is difficult to perform using
609 individual boreholes. Borehole measurements have to include period of stabilization
610 of permafrost temperature that at 1 m depth may last even up to 250 days
611 (Gregersen and Eidsmoen 1988) leading to significant delay in obtaining reliable data
612 on thermal state of the permafrost.

613

614 **Conclusions**

615 We draw seven conclusions from this study

- 616 1. Very low resistivity observed in the intertidal zone exclude existence of submarine
617 permafrost at least in the nearshore zone.
- 618 2. Low ground resistivity continuing inland in deeper ground sections, impossible to
619 explain with lithological changeability, provide evidence for strong influence of
620 temperature and salinity of the sea on the permafrost base.
- 621 3. The shape of the permafrost base in close proximity to the sea reminds a wedge
622 directed towards the shoreline.
- 623 4. Resistivity changes found in the same profile line at different times document the
624 existence of the active layer existing from the side of the permafrost base.
- 625 5. The coastline shape configuration and exposure to wave and tidal action have a
626 significant influence on the formation of deeper (>10 m) permafrost levels.

627 6. The effective interpretation of the active layer is possible with the use of small
628 electrode spacing of 1 or 1.5 m during the ERT measurements.

629 7. The ERT measurements allowed monitoring of changes in spatial distribution of
630 active layer and base of the coastal permafrost.
