The Pacific cold tongue annual cycle in sea surface temperature is presumed to be driven by Earth's axial tilt¹⁻⁵ ('tilt effect') and thus its phasing should be fixed relative to the calendar. However, its phase and amplitude change dramatically and consistently under various configurations of orbital precession in several Earth System models. Here we show that the cold tongue possesses another annual cycle driven by the variation in Earth-Sun distance ('distance effect') from orbital eccentricity. As the two cycles possess slightly different periodicities⁶, their interference results in a complex evolution of the net seasonality over a precession cycle. The amplitude from the distance effect increases linearly with eccentricity, and is comparable to the amplitude from the tilt effect for the largest eccentricity values over the last million years ($e \sim 0.05$)⁷. Mechanistically, the distance effect on the cold tongue arises through a seasonal longitudinal shift in the Walker circulation and subsequent annual wind forcing on the tropical Pacific dynamical ocean-atmosphere system. The finding calls for a re-assessment of our current understanding of the Pacific cold tongue annual cycle, and re-evaluation of tropical Pacific paleoclimate records for annual cycle phase changes.

The Pacific cold tongue is an integral part of the tropical Pacific coupled ocean - atmosphere system and possesses a dominant annual cycle in sea surface temperature (SST) ([Extended Data Figure 1](#)), even though insolation at the equator peaks twice a year¹([Extended Data Figure 2a](#)). Prevailing theory developed in the 1990s¹⁻⁵ explained the annual cycle through the following sequence: An annual mean equatorial cold tongue arises through easterly trades that shallow the thermocline to the east, allowing upwelling to bring cold water from below the thermocline into the mixed layer⁸. Because of the northward bias of the Pacific Intertropical Convergence Zone (ITCZ)⁹ southeasterly trades cross the equator throughout the year. Their strength changes over the course of a year, controlled by the differential heating between hemispheres resulting from the tilt effect, with a delay due to the thermal inertia of the ocean. The southeasterly trades are strongest in boreal fall ([Extended Data Figure 1b](#)) and cause surface waters to cool at the eastern boundary through coastal upwelling that propagates westwards along the equator, facilitated by zonal ocean-atmosphere feedback^{10,11}; the same winds also drive increased surface heat fluxes and vertical mixing at the equator, further cooling the equatorial surface ocean^{3,10}. Conversely when the southeasterly trades weaken in boreal spring, the cold tongue is warmer ([Extended Data Figure 1c](#)). Since the cold tongue annual cycle is controlled by the tilt effect, its phase relative to the calendar year should thus be relatively immutable since both are timed to the equinoxes.

This prevailing view was recently challenged by an Earth system model¹² (GFDL CM2.1; [see Methods section 1](#)) simulating a remarkable change in the phase of the cold tongue annual cycle with the longitude of perihelion (the position of perihelion relative to the moving vernal equinox, see [Figure 1](#); hereafter **LOP**). The eccentricity was set to 0.0493, being the maximum attained over the last 600,000 years⁷, and approximately three times as large as the modern-day value ([Extended Data Figure 2b](#)). When the LOP was altered from 90° (perihelion at winter solstice) to 180° (perihelion at vernal equinox), the coldest month changed from August to October; then to January for LOP at 270° (perihelion at summer solstice), and then to May for LOP at 0° (perihelion at autumn equinox) ([figure 2, top row](#)). The amplitude of the annual cycle also changed dramatically, being largest for LOP at 90° and 180° and smallest with LOP at 0°, despite obliquity being fixed. No straightforward relationship is discernible when the cold tongue annual cycle behavior is compared with its corresponding seasonal cycle of insolation at the equator ([Extended Data Figure 2c-f](#)). Similar cold tongue behavior is found in identical set

of simulations performed with two other Earth System models (iCESM 1.2 and HadCM3; see Methods section 1) (figure 2, 2nd and 3rd rows respectively) and with a fourth model (EC Earth; Extended Data Figure 3) performed with slightly different orbital parameters (see Methods section 1).

Cold tongue response to eccentricity

When eccentricity is set to zero and annual cycle forcing arises solely from the tilt effect, the simulated Pacific cold tongue seasonality behaves in a way that is consistent with prevailing theory, with the cold peak timed to boreal fall and warm peak to boreal spring (figure 2, last column). We show that as orbital eccentricity is introduced, another cold tongue annual cycle emerges. Simulations with an Earth system model (CESM 1.2 - see Methods section 1) spanning the range of LOP are undertaken at three eccentricities (e) - 0.01, 0.02 and 0.04 - covering the typical range over the last million years⁷ (hereafter the **CESM LOP** simulations - see Methods section 1). All other boundary conditions are set to preindustrial (1850AD), including obliquity.

The cold tongue annual cycle shows two distinct features as the longitude of perihelion is varied (figure 3a; for $e = 0.04$): a change in the timing of peaks and troughs, and a marked reduction in amplitude near $\text{LOP} = 0^\circ$. We fit the results of figure 3a with the sum of two cosines, one whose phase is fixed to the calendar representing the tilt effect, and the other whose phase changes linearly with the LOP representing the distance effect. We also include a semiannual cycle with its phase fixed to the calendar, to account for insolation peaking at the equator twice a year during the equinoxes (Extended Data Figure 2a).

$$CT_{fit} = A_T \cos\left(\left(\frac{2\pi}{12}\right)(m - p_T)\right) + A_D \cos\left(\left(\frac{2\pi}{12}\right)(m - p_D) - \left(\frac{\text{LOP}\pi}{180}\right)\right) + A_S \cos\left(\left(\frac{2\pi}{6}\right)(m - p_S)\right) \quad [1]$$

where A_T and p_T are the amplitude and phase of the annual cycle for the Tilt effect; likewise, A_D and p_D for the Distance effect, and A_S and p_S for the Semiannual cycle. m is the numerical months of the year from 0 to 12 (with 0.5 corresponding to mid-January), and LOP is the longitude of perihelion, in degrees.

The best-fit surface to the data (figure 3b; also see Methods section 2) captures its salient features, including the change in phase and reduction in amplitude near $\text{LOP} = 0^\circ$. The tilt and

distance annual cycles are comparable in amplitude ([figure 3d, e](#)), but the semiannual contribution is relatively small ([figure 3f](#)). The same fitting exercise but with $e = 0.01$ and 0.02 ([Extended Data figure 4](#)) shows an essentially unchanged annual cycle contribution from the tilt effect and semiannual cycle ([Table 1](#)), but the amplitude of the distance effect annual cycle decreases linearly with decreasing eccentricity ([figure 3c](#)). A similar outcome occurs when fitting equation 1 to a simulation with $e = 0$ (the *tilt-only* run), assuming $A_D = 0$ ([Table 1](#)). The consistency in the fitted parameters lends confidence to the validity of our model.

The above results are consistent with cold tongue seasonality arising from the sum of the tilt and distance effect annual cycles. As the duration of the distance effect annual cycle is slightly longer than that of the tilt effect (currently by ~ 25 minutes)⁶, the two interfere resulting in a complex evolution of the net cold tongue annual cycle with orbital precession. The amplitude from the distance effect increases linearly at ~ 0.23 K per 0.01 eccentricity units ([figure 3c](#)), meaning that even at today's low eccentricity the amplitude from the distance effect is $\sim 1/3$ of that from the tilt effect. For the largest orbital eccentricities over the last million years ($e > 0.05$)⁷, the distance effect amplitude is as large or even larger than the tilt effect amplitude.

We confirm this interpretation through a simulation that removes the tilt effect by setting obliquity to 0° (the *distance-only* run); we use $e = 0.05$ (and $LOP = 0^\circ$) such that the distance effect amplitude approximately matches the tilt effect amplitude. In contrast to the annual cycle in the tilt-only run ([Extended Data figure 5c](#)), the distance-only run shows an annual cycle with a cold peak in early May and warm peak in mid-late October ([Extended Data figure 5b](#)). When the two annual cycles are summed, they produce a cold tongue seasonality that resembles the simulation with both distance and tilt effects present ([Extended Data figure 5a and d](#)). With both eccentricity and obliquity set to zero (the *zero annual forcing run*), the cold tongue annual cycle essentially disappears ([Extended Data figure 5e](#)).

Equatorial wind and thermocline changes

Previous model studies using mid-Holocene orbital conditions (corresponding to $LOP \sim 0^\circ$)¹²⁻¹⁴ have suggested that the cold tongue annual cycle changes are dynamically induced through equatorial thermocline changes. Erb et al. (2015)¹² show in their $LOP = 0^\circ$ simulation that in boreal spring, weakening trades in the western equatorial Pacific coincide with a deeper

equatorial thermocline, the latter of which propagates eastwards to warm the eastern equatorial SST by boreal fall. Thermodynamic SST changes by direct insolation forcing also contribute to the fall warming. The opposite occurs for the other half of the year. We note that the prevailing theory for the cold tongue annual cycle does not prescribe a role to seasonal variations in the thermocline².

We similarly examine equatorial wind stress and thermocline changes in the CESM LOP simulations. Using the $e = 0.04$ case, we find a clear eastward propagation of the thermocline anomaly originating from the western Pacific for all LOP cases, provided that the tilt effect contribution is removed beforehand ([Extended Data figure 6, contours](#)). Zonal wind stress changes in the western equatorial Pacific precede thermocline anomalies for all LOP cases, with anomalous westerlies corresponding to a deeper thermocline, and vice versa ([Extended Data figure 6, shaded](#)). Thus, the distance effect annual cycle appears to involve the same coupled ocean-atmosphere dynamics and equatorial thermocline propagation that gives rise to the El Niño-Southern Oscillation (ENSO)¹⁵.

We confirm this interpretation using a set of simplified model simulations ([see Methods section 4](#)). First, we obtain the distance effect wind response by imposing the appropriate orbital conditions (and $\text{LOP} = 0^\circ$) in CESM1.2 with the ocean component replaced by a ‘slab’ ocean that incorporates thermodynamic ocean-atmosphere interactions from surface fluxes but not the dynamical thermocline evolution. They generate a seasonal cycle of zonal wind anomalies in the equatorial western Pacific that is independent of the dynamic ocean-atmosphere coupling, with peak anomalous westerlies occurring at the end of April ([Extended Data figure 7a](#)). These winds are then imposed as an annually repeating forcing on an intermediate coupled model¹⁶ (ICM) that contains the essential dynamics to simulate the ENSO. The ICM responds by producing a cold tongue annual cycle with the peak warm phase occurring 3-4 months after the peak anomalous westerlies in the western Pacific ([Extended Data figure 7a](#)). As in the CESM LOP simulations, eastward-propagating thermocline variations link the zonal wind annual cycle in the western Pacific to the annual cycle of the cold tongue in the ICM ([Extended Data figure 7b](#)). We conclude that the coupled dynamics that generates ENSO are also integral to the distance effect cold tongue annual cycle. These coupled dynamics arise as a forced response to the annual cycle in zonal wind stress changes in the western Pacific that arise from a thermodynamic response to the distance effect.

The peak warm phase of the cold tongue in the distance-only run occurs 4-5 months after the peak anomalous westerlies ([Extended Data figure 5b](#)), a longer lag time than in the ICM ([Extended Data figure 7a](#)). We attribute this difference to the direct thermodynamic response of the distance effect insolation on SST, which has its peak warm phase ~7 months after the peak westerlies ([Extended Data figure 7c](#)); this would act to delay the timing of the warm peak in the cold tongue.

Zonal shift in the Walker circulation

The western Pacific wind changes result from a seasonal cycle in the longitudinal position of the Walker circulation driven by the distance effect. In the distance-only run, the equatorial easterlies in the western Pacific exhibit an annual cycle and essentially vanish between March and June ([figure 4a, black contours](#)). This feature contrasts with the zero annual forcing run where the equatorial Pacific zonal winds are always easterly. The cold tongue is at its coldest ([figure 4a, shaded](#)) when the easterlies vanish, indicating that the winds are not being driven by the cold tongue SST. Rather, the vanishing easterlies result from an eastward shift of the main uplift region of the Walker circulation ([Extended Data figure 8c](#)), accompanied by an increase in the precipitation over the equatorial western Pacific and decrease over the Maritime Continent ([Extended Data figure 8a](#)). The opposite occurs during September-December ([Extended Data figure 8b and d](#)).

We use an atmospheric energy flux analysis¹⁷ to confirm the Walker circulation shift and diagnose its causes ([see Methods section 5](#)). This analysis links the longitude of its main uplift region to the position of zero and diverging zonal energy flux, aka the energy flux prime meridian (EFPM). For the zero annual forcing run, the EFPM over the equatorial western Pacific stays at ~150°E throughout the year ([figure 4a, green dashed line](#)). With eccentricity increased to 0.05, a distance effect annual cycle in the EFPM emerges with an eastward shift between March-June following aphelion, and a westward shift between September-December following perihelion ([figure 4a, green solid line](#)); note that it aligns well with the zonal wind stress changes over the western equatorial Pacific. The EFPM change is caused by a zonal dipole in the energy flux potential ([figure 4b and c, shading](#)) between the hemisphere extending from the Maritime Continent through the Pacific (the *Marine hemisphere*, being mostly ocean),

with the hemisphere extending from South America through to the Indian ocean (the *Continental hemisphere*, having relatively more land). For March-June following aphelion, there is increased zonal atmospheric energy transport from the Marine to the Continental hemisphere ([figure 4b, vectors](#)) and the EFPM (and hence the Walker uplift region) shifts eastwards. The opposite occurs in September-December following perihelion ([figure 4c](#)). Other diagnostics of the large-scale atmospheric circulation – upper tropospheric velocity potential and surface pressure – confirm the seasonal zonal shift in the Walker circulation and the global east-west hemispheric nature of its origins ([Extended Data figure 8e-h](#)).

The zonal energy transport arises from the differing thermal response of the two hemispheres to the distance effect. For September-December following perihelion, the surface of the Marine hemisphere absorbs relatively more of the increased sunlight than that of the Continental hemisphere, implying that the Marine hemisphere fluxes less energy into the overlying atmosphere than the Continental hemisphere. Because tropical atmospheric dynamics act to rapidly homogenize tropospheric temperature differences¹⁸, there is increased zonal atmospheric energy transport from the Continental to the Marine hemisphere, and the Walker circulation shifts to the west. The opposite occurs in March-June following aphelion. This behavior is analogous to the latitudinal migration of the ITCZ in response to atmospheric energy transport changes between the northern and southern hemispheres from the tilt effect^{19,20}.

Implications

Our findings call for a re-evaluation of mechanisms underpinning the Pacific cold tongue annual cycle, in particular thermocline changes. The distance effect may have escaped attention as the current annual cycle resembles that from the tilt effect alone, and thus does not pose a challenge to the prevailing theory. It also begs the question: to what extent does the distance effect contribute to the seasonal cycle of other regional climates? This question is rarely asked²¹, but this study demonstrates how new insights in the Earth's seasonal cycle are revealed if the tilt and distance effects are considered separately.

We also argue for a reexamination of tropical Pacific paleoclimate records for changes to the annual cycle. Paleoclimate studies examining tropical Pacific records on orbital timescales have largely framed cold tongue changes in terms of ENSO²²⁻²⁷, though attempts have been

made to separate amplitude changes into ENSO and annual cycle contributions^{25,28-30}. Determining the phasing of paleoproxy signals relative to the calendar year is more challenging, and we are not aware of any attempts in this regard. It requires records that resolve the annual cycle, and a marker to affix the calendar. The semiannual cycle can potentially serve as a marker, as it is timed to equinoxes. We also note that a change in the cold tongue annual cycle may itself cause changes to ENSO, since feedbacks that govern the latter depend on the seasonal cycle^{31,32}.

Finally, we speculate on the implications to the global paleoclimate. The tropical Pacific is thought to play a defining role in paleoclimate on orbital timescales^{33,34}, given its responsiveness to forcing and global reach through teleconnections. The phase of precession has been linked to many regional paleoclimate changes around the globe, prominent examples being peak monsoon intensity^{35,36}, and the timing of the Ice Ages³⁷⁻³⁹. The implicit assumption is that the precession influence works through direct insolation changes at the latitude of the regional climate. However, our results suggest that the tropical Pacific may also be capable of remotely orchestrating precession changes around the globe, through altering the cold tongue annual cycle.

Table 1. Fitted coefficients for equation 1 to the cold tongue SST annual cycle variation with LOP in the CESM LOP simulations, for various eccentricity values. The cold tongue SST is averaged over 220-270°E, 6°S-6°N. For zero eccentricity, A_D is assumed to be zero. The values in brackets indicate the 95% confidence bounds. Note the consistency in the coefficients for A_T , A_S , p_T , p_S and p_D across various eccentricities.

Figure 1. Schematic of the Earth's orbital configuration. The Earth's orbit around the Sun (marked S) is elliptical with the Sun at one focal point, and with the closest approach at perihelion (at a distance r_p) and furthest at aphelion (r_a). The direction of the orbit is counterclockwise. The eccentricity e , defined in the figure, measures how elliptical the orbit is: $e = 0.0493$ is used for the simulations reported in figure 2, approximately three times larger than the modern-day value. The equinox and solstice points are named following Northern hemisphere seasons. The longitude of perihelion (LOP) relative to the moving vernal equinox is defined (following figure 8 of Berger 1988³⁸) as the angular distance from vernal equinox to perihelion following Earth's orbit ($\tilde{\omega}$, in degrees), subtracted by 180° . Thus, $LOP = 90^\circ$ and 180° if perihelion occurs during winter solstice and vernal equinox, respectively. Perihelion as drawn in the schematic is positioned for modern day, with a $LOP \sim 103^\circ$ and date around January 3. Since the distance effect annual cycle (from perihelion to perihelion, aka the *anomalistic year*, 365.259636 days⁶) is slightly longer than the tilt effect annual cycle (from equinox to equinox, aka the *tropical year*, 365.242189 days⁶), the LOP increases over time. A complete revolution of the LOP is the *precession cycle*, approximately 22,000 years³⁸. Note that the Gregorian calendar is referenced to the vernal equinox, with its rule for leap days designed to resynchronize the calendar year with the tropical year.

Figure 2. Annual cycle of equatorial Pacific sea surface temperatures for three different Earth System models show a remarkable and consistent seasonal variation with the longitude of perihelion. Plotted is the climatological monthly mean SST averaged over 6°S - 6°N , for (top row) GFDL CM2.1¹², (2nd row) iCESM 1.2⁴⁰, and (3rd row) HadCM3. The numbers on the top row denote the longitude of perihelion (where 90° = perihelion at winter solstice, 180° = at vernal equinox, 270° = at summer solstice, and 0° = at autumn equinox). The last column ($e = 0$) denotes simulations with eccentricity set to zero. To facilitate comparison, an offset is added to each panel so that the annual mean SST averaged over $145\text{-}275^{\circ}\text{E}$ is the same as for the observational data as shown in Extended Data figure 1a, 27.44°C . Note that the time (y) axis here and in other figures is such that 0 is the start of the year and 12 is the end; mid-January is thus 0.5.

Figure 3. Variation of the cold tongue annual cycle to LOP arises from the sum of the tilt and distance effect contributions. (a) Cold tongue SST (averaged over 6°S - 6°N , 220 - 270°E) annual cycle for $e = 0.04$ with varying longitude of perihelion. The annual mean is removed from each annual cycle prior to plotting. (b) Least-square surface fit of the data in (a), using equation 1. (c) Fitted coefficients of the distance effect amplitude (A_D , black symbols), and the least-square linear fit to the data forced through the intercept (dashed line). The bars indicate the 95% confidence bounds for each A_D fit. For comparison, the fitted coefficients of the tilt effect amplitude (A_T) are shown in red. The green dot indicates the distance effect amplitude for eccentricity at preindustrial ($e = 0.0167$). (d-f) Contributions of the fit in (b) from (d) tilt effect, (e) distance effect, and (f) semiannual cycle. The same color scale is used for panels a, b, d, e, and f.

Figure 4. The distance effect on the longitude position of the Walker circulation as diagnosed by the energy flux potential. (a) Equatorial Pacific zonal wind stress (black contours, contour interval $1 \times 10^{-2} \text{ N/m}^2$; dashed contours are negative, and zero contour not shown) and sea surface temperature (shaded) averaged over 6°S - 6°N for the distance-only run (obliquity = 0, $e = 0.05$, LOP = 0°). Positive values of wind stress correspond to westerly winds. Since the focus is on the cold tongue, sea surface temperature is only shown east of the date line; also, an offset is added so that the annual mean SST averaged over 145 - 275°E is the same as for the observational data as shown in Extended Data figure 1a, 27.44°C . The solid green line shows the energy flux prime meridian (EFPM) over the western Pacific for the distance-only run, and the dashed green line for the zero annual forcing run. (b) Energy flux potential (shaded) averaged over March-June, for the difference between the distance-only and zero annual forcing runs (the former minus the latter). The vectors correspond to the difference in the divergent horizontal atmospheric energy transport. (c) same as (b) but for September-December. See Methods section 5 for details on the calculations. The M_Map package⁴¹ is used to generate the maps in (b) and (c), using coastline data from the Global Self-consistent, Hierarchical, High-resolution Geography Database⁴².

Methods

1. *Earth System Model simulations*

GFDL CM2.1: The simulations are as reported in Erb et al. (2015)¹². The Geophysical Fluid Dynamics Laboratory (GFDL) climate model Version 2.1⁴³ is used at 2x2.5° in the atmosphere, and 1x1° in the ocean but progressively to 1/3 degree resolution in the meridional direction at the equator. Boundary conditions are set to preindustrial except for eccentricity which is set to $e = 0.0493$, and LOP is set to 0, 90, 180, and 270 ° respectively (labeled AE, WS, VE, and SS in Erb et al. (2015)¹²). Obliquity is set to 23.439°. A simulation with zero eccentricity is also done. Each simulation is 600 years long, and the average of the last 100 years used for the monthly climatology. The calendar was converted to fixed angle from the standard monthly mean output using the method of Pollard and Reusch (2002)⁴⁴.

iCESM 1.2: The simulations are as reported in Tabor et al. (2018)⁴⁰. This model uses the Community Earth System Model (CESM) version 1.2 but with the inclusion of a water isotope tracer⁴⁵. The water isotope tracers do not affect the physical climate, so the simulated physical climate is comparable to the CESM 1.2 which has been shown to well simulate historical and present-day climate⁴⁶. The atmosphere and land are on a 1.9°x2.5° finite-volume grid, and ocean and sea ice on a nominal 1° rotated pole grid (gx1v6). Orbital configurations are as in the AE, WS, VE and SS cases in Erb et al. (2015)¹², with eccentricity set to 0.0493 and obliquity to 23.44107°. Other boundary conditions are set to preindustrial. A fifth simulation is performed with eccentricity set to zero. Simulations were run for a total of 1050 years. The first 500 years were run using CESM1.2 without water isotope tracers followed by an additional 550 years using water isotope tracers. All simulations are near equilibrium with top-of-atmosphere radiation imbalances less than 0.15 Wm⁻². For this study, all five simulations were extended for 50 years, and those data were used to calculate the climatology. The calendar was converted to fixed angle using daily data, following the calendar conversions of Pollard and Reusch (2002)⁴⁴.

HadCM3: The simulations use the version HadCM3B_M2.1N⁴⁷. This is a version of the original HadCM3 model^{48,49}. The atmospheric component HadAM3B has a Cartesian grid with a horizontal resolution of 96 × 73 grid points (3.75° longitude × 2.5° latitude), and the ocean component has a resolution of 288 × 144 grid points (1.25° longitude × 1.25° latitude).

Boundary conditions are set to preindustrial except for eccentricity which is set to $e = 0.0493$,

and the longitude of perihelion is set to 0, 90, 180, and 270°, respectively. Obliquity is set to preindustrial at 23.439°. A simulation with zero eccentricity is also done. Each simulation is 500 years long, and the average of the last 100 years used to form the monthly climatology.

EC Earth: We use the Pmin, Pmax, and Tmin simulations of EC Earth as performed in Bosmans et al. (2015)⁵⁰. EC Earth 2.2 is a fully coupled model with an atmospheric horizontal resolution of T159 (roughly 1.125° x 1.125°) and 62 vertical levels, and ocean model at 1° resolution and 42 vertical levels. The Pmin simulation sets obliquity at 22.08°, eccentricity at 0.056, and LOP at 264.04°; the Pmax simulation has the same obliquity, eccentricity at 0.058, and LOP at 86.5°. The eccentricity is thus slightly larger than the simulations shown in [figure 2](#), and the LOP is not exactly at 270° and 90° but are sufficiently close for our purposes for a qualitative comparison. The Tmin simulation is a zero eccentricity simulation with obliquity set to 22.08°, to be compared to the $e = 0$ simulations in [figure 2](#). Each simulation is 100 years, and the last 50 years is used to form the climatology.

CESM LOP and idealized simulations: Simulations are done with the Community Earth System Model version 1.2 (hereafter CESM 1.2)⁴⁶ at 1.9°x2.5° finite-volume grid, and ocean and sea ice on a nominal 1° rotated pole grid (gx1v6). Each simulation is for 25 years, and the last 20 years are averaged to form a seasonal climatology. Simulations varying the LOP are done at intervals of 30° from 0° to 330°, and for 3 eccentricities: 0.01, 0.02, and 0.04. Obliquity is set to 23.439°. All other boundary conditions are set to preindustrial. Note that the simulated cold tongue changes here are qualitatively like the longer iCESM 1.2 simulations, despite the short integration time ([Extended Data figure 9](#)). There are also 4 idealized simulations: *tilt and distance*, where eccentricity is set to 0.05 and obliquity to 23.439° (and LOP=0°); *tilt-only*, where eccentricity is set to zero and obliquity to 23.439°; *distance-only*, where obliquity is set to zero and eccentricity to 0.05 (and LOP=0°); and *zero annual forcing* where both obliquity and eccentricity are set to zero. See [Extended Data table 1](#) for a list of simulations.

Fixed angle calendar: A calendar adjustment was applied to the CESM LOP and idealized simulations to account for the shift in some dates of equinoxes and solstices when LOP is altered under high eccentricity⁵¹, by assigning each month to 30° of arc in the orbit. The method of Pollard and Reusch (2002)⁴⁴ was used to alter monthly mean output from the standard calendar to fixed angle, using the vernal equinox as the tie point. The GFDL CM2.1 and iCESM 1.2 calendars were already converted to fixed angle from their respective original applications^{12,40}.

The conversion results in a relatively minor modification to the numerical timing of the months; for this reason, the HadCM3 and EC Earth calendars were not converted to fixed angle, noting that those outputs were only used for a qualitative comparison.

2. *Surface fitting*

The surface fit of [figure 3a](#) (and [Extended Data figure 4a and c](#)) using equation 1 is done in MATLAB R2021a using the function ‘fit’ and specifying equation 1 as the model using the function ‘fittype’, setting m and LOP as the independent variables; otherwise, default settings are used. Both functions are found in the curve fitting toolbox⁵². The method uses a nonlinear least squares minimization algorithm (Trust-Region Reflective method) to determine the fit; amplitudes (A_T , A_D , A_S) are allowed to range between 0-3K, and phase (p_T , p_D , p_S) between 0 and 12.

3. *Calculation of equatorial thermocline temperature*

We first extract the depth of the 20°C isotherm in the annual mean climatological potential temperature averaged between 6°N-6°S. There is a depth value for each longitude point across the equatorial Pacific, and we use this as the reference thermocline depth. Using monthly climatological potential temperature, we then extract the potential temperature (averaged between 6°S-6°N) at the reference thermocline depth. For each longitude point, we obtain 12 potential temperature values representing the monthly climatological variation in potential temperature at mean thermocline depth.

4. *Simulations with an intermediate coupled model of the tropical Pacific*

We use an intermediate coupled model¹⁶ (ICM) of the tropical Pacific coupled ocean-atmosphere system that has been extensively used for El Nino-Southern Oscillation (ENSO) studies. It is an anomaly model, and the mean state is prescribed. The atmosphere is a Gill⁵³ model representing the global tropical atmosphere, and with heating parameterized to SST and to convergence feedback. The ocean model is a reduced-gravity 1.5-layer model with an embedded mixed layer, and spans only across the tropical Pacific (124°W - 80°W). The atmosphere is coupled to the ocean through wind stress, and the reverse through SST. The reader is referred to Battisti

(1988)¹⁶ for details. External wind forcing on the ICM is applied similar to the method used in Thomas and Vimont (2016)⁵⁴, except that in this case the wind forcing is annually repeating.

We first generate distance effect wind forcing for the ICM by running two CESM1.2 simulations with $e = 0$ and 0.04 respectively; LOP is set to 0° , obliquity to 23.439° , and all other boundary conditions to preindustrial. The CESM1.2 simulations here uses the thermodynamic ‘slab’ ocean rather than the full dynamical ocean; this allows for the simulation of tropical Pacific climate changes to the orbital forcing in the absence of the ocean-atmosphere dynamics as contained in the ICM. Simulations are 25 years long, with the last 20 used to form the monthly climatology. We extract the distance effect wind forcing from the difference ($e = 0.04$ minus $e = 0$) of the lowest atmospheric level winds from the respective climatologies. The resulting annually repeating wind forcing is then imposed as an external forcing to the ICM domain. The ICM is run for 100 years, and results are averaged over the last 50 years to form the monthly climatological fields shown in [Extended Data figure 7](#).

5. *Atmospheric energy flux analysis*

The atmospheric energy flux potential analysis^{17,55} relates zonal and meridional shifts in tropical rainfall to horizontal atmospheric energy transports, a 2-D generalization of the zonal mean energetic approaches¹⁹. An energy flux potential χ is defined such that its gradient is the divergent component of the horizontal atmospheric energy transport:

$$(\partial_x \chi, \partial_y \chi) = (u_h, v_h) \quad [2]$$

The energy flux potential is approximately related to the energy flux into the atmospheric column as (see Boos and Korty (2016)¹⁷ for a derivation)

$$\nabla^2 \chi \approx E + H + R \quad [3]$$

where E is the surface latent heat flux, H is the surface sensible heat flux, and R is the column radiative heating (i.e. the sum of the top of the atmosphere and surface shortwave and longwave energy fluxes) where the fluxes are defined as positive when directed into the atmosphere. The ascending branches of both meridional and zonal overturning circulations occur along an energy

flux equator (EFE) and energy flux prime meridian (EFPM), respectively. An EFE is a latitude for which $v_h = 0$ and $\partial_y v_h > 0$, and an EFPM is a longitude for which $u_h = 0$ and $\partial_x u_h > 0$.

To calculate the energy flux potential, we first calculated the monthly mean net energy input into the atmospheric column using the sum of surface latent heat flux, surface sensible heat flux, and surface and top-of-atmosphere longwave and shortwave radiation fluxes. The Laplacian solver from the windspharm Python package⁵⁶ is then used to solve the Laplace equation (3) on a spherical surface. We then used the package's gradient function to calculate u_h and v_h for each month from the corresponding energy flux potential. To calculate the EFPM shown in figure 4a, u_h is averaged between 10°S-10°N, and a 5-point smoothing is applied twice longitudinally to the resulting field. The EPFM is then identified, for each month, at the longitude where $u_h = 0$.

Data Availability statement

The iCESM 1.2, HadCM3, CESM 1.2, and ICM output variables used in this study is available at Chiang et al. (2022)⁵⁷ (<https://doi.org/10.6078/D1VB0G>). GFDL CM2.1 model output is available at Erb et al. (2018)⁵⁸, and EC Earth output at Bosmans (2019)⁵⁹.

Code availability statement

The CESM 1.2 code is publicly available at <https://www.cesm.ucar.edu/models/cesm1.2/> . Analytical codes used in this paper is available in Chiang et al. (2022)⁵⁷ (<https://doi.org/10.6078/D1VB0G>) .

Acknowledgements

The authors thank David Battisti for providing the ICM code; William Boos for providing code
for the energy flux diagnostic; David Pollard and Michael Erb for providing code for the fixed-
angle calendar conversion; Sarah White and River Shen for advice on paleoproxy records; and
Bryan Raney and Joyce Bosmans for providing the GFDL and EC Earth model output,
respectively. J.C.H.C. acknowledges support from a Visiting Professorship at Academia Sinica,
funded by the Ministry of Science and Technology, Taiwan, under grant number 110-2811-M-

001-554. A.R.A. acknowledges support from National Science Foundation award 1903640. C.R.T. acknowledges funding from the National Center for Atmosphere Research Advanced Study Program postdoctoral fellowship. This research used the Savio computational cluster resource provided by the Berkeley Research Computing program at the University of California, Berkeley (supported by the UC Berkeley Chancellor, Vice Chancellor for Research, and Chief Information Officer). High-performance computing support on Cheyenne (doi:10.5065/D6RX99HX) was provided by NCAR's Computational and Information Systems Laboratory, sponsored by the National Science Foundation.

Author contributions

J.C.H.C., A.R.A., and A.J.B. conceived the study. J.C.H.C. conducted the CESM simulations and led the data analysis, writing of the manuscript, and design of figures. D.J.V. and A.R.A. undertook the intermediate coupled model simulations and analysis. P.A.N. provided the energy flux analysis. W.H.G.R. and C.R.T. conducted the HadCM3 and iCESM 1.2 model simulations, respectively. All authors contributed to the writing of this manuscript.

Extended Data Table/Figures

Name of simulation	Eccentricity	Longitude of Perihelion (LOP)	Obliquity
CESM LOP	0.01, 0.02, and 0.04	0° to 330° in steps of 30°	23.439°
Tilt and Distance	0.05	0°	23.439°
Distance-only	0.05	0°	0°
Tilt-only	0.00	0°	23.439°
Zero annual forcing	0.00	0°	0°

Extended Data Table 1: Summary table of CESM 1.2 simulations used in this study and their orbital configurations. All other boundary conditions are set to preindustrial (1850AD). All simulations are 25 years long, and the last 20 are used to calculate the climatology. Note that the simulations used for [figure 2](#) are not listed here; details of those simulations are in [Methods](#).

Extended Data Figure 1. Modern-day observed Pacific cold tongue annual cycle. (a) SST averaged over 6°S-6°N, showing the cold tongue annual cycle with the cold peak in boreal fall and warm peak in boreal spring. Note that the time axis is such that 0 is the start of the year and 12 is the end; mid-January is thus 0.5. (b-c) SST and 10m winds for (b) October (cold peak), and (c) April (warm peak). Data is from ERA-Interim⁶⁰, averaged over 1979-2018. The M_Map package⁴¹ is used to generate the maps for (b) and (c), using coastline data from the Global Self-consistent, Hierarchical, High-resolution Geography Database⁴².

Extended Data Figure 2. The seasonal cycle of insolation at the equator for different orbital configurations, including those used in figure 2. In all cases, downward solar radiation at top-of-atmosphere is averaged over 6°S - 6°N , and the blue dashed line is for the tilt-only ($e=0$) case. **(a)** Preindustrial case. **(b)** difference from the tilt-only case for LOP=90°, $e=0.0493$ (black line), and preindustrial (green line). **(c)** LOP=0°, $e=0.0493$. **(d)** LOP=90°, $e=0.0493$. **(e)** LOP=180°, $e=0.0493$. **(f)** LOP=270°, $e=0.0493$. Insolation data is from the GFDL CM2.1 simulations of Erb et al. (2015)¹². Panel (b) shows the contrast in the amplitude of insolation changes between the $e=0.0493$ case ($\sim 42\text{W/m}^2$) and the preindustrial case ($\sim 15\text{W/m}^2$) where the eccentricity is $\sim 1/3$ as large.

Extended Data Figure 3. Cold tongue annual cycle in EC Earth also shows consistent variation with changing LOP. Plotted is the climatological monthly mean SST averaged over 6°S-6°N (same as Figure 2) for the (a) Precession maximum, minimum obliquity (Pmax), (b) Precession minimum, minimum obliquity (Pmin), and (c) Minimum obliquity with circular orbit (Tmin) runs in Bosmans et al. (2015)⁵⁰. To facilitate comparison, an offset is added to each panel so that the annual mean SST averaged over 145-275°E is the same as for the observational data as shown in [Extended Data figure 1a](#), 27.44°C. The orbital parameters are slightly different, but Pmax corresponds approximately to the LOP = 90° simulation, Pmin to LOP = 270° simulation, and Tmin to the $e = 0$ simulation. The column positioning of the panels corresponds to the equivalent LOP or $e = 0$ case in [figure 2](#). See [Methods](#) for the orbital parameters and details of the simulations.

Extended Data Figure 4. Variation of the cold tongue SST annual cycle to LOP in CESM LOP for $e = 0.01$ and $e = 0.02$, and their fits to equation 1. (a) Cold tongue SST (averaged over 6°S - 6°N , 220 - 270°E) for $e = 0.01$ and varying longitude of perihelion. The annual mean is removed prior to plotting. (b) Least-square surface fit of the data in (a), using equation 1. (c) and (d): same as (a) and (b) respectively, except for $e = 0.02$. See [Table 1](#) for the fitted coefficients.

Extended Data Figure 5. CESM 1.2 annual cycle of equatorial Pacific SST under different combinations of tilt and distance effects. Plotted is climatological monthly mean SST averaged over 6°S - 6°N across the Pacific. In all cases, $\text{LOP} = 0^{\circ}$. To facilitate comparison, an offset is added to each panel so that the annual mean SST averaged over $145\text{-}275^{\circ}\text{E}$ is the same as for the observational data as shown in [Extended Data figure 1a](#), 27.44°C . **(a)** $e = 0.05$, obliquity = 23.439° (tilt and distance run); **(b)** $e = 0.05$, obliquity = 0° (distance-only run); **(c)** $e = 0.00$, obliquity = 23.439° (tilt-only run); **(d)** sum of the annual cycles of (b) and (c), added to the annual mean of (a); and **(e)** $e = 0$, obliquity = 0° (zero annual forcing run).

Extended Data Figure 6. Equatorial thermocline response in the CESM LOP simulations connects the western equatorial Pacific zonal wind stress change to cold tongue changes.

LOP cases (a) 90°, (b) 180°, (c) 270°, and (d) 0° are shown. Contours show the 6°S-6°N averaged temperature anomaly at mean thermocline depth for $e=0.04$, for the stated LOP. The temperature averaged across all LOP cases is first subtracted out, to remove the influence of the tilt effect from the thermocline. The contour interval is 0.5K, and dashed values are negative; the zero contour is not shown. For clarity, only values east of 170°E are plotted. The eastward propagation of thermocline anomalies is visually apparent. Shading represents the corresponding zonal wind stress anomaly averaged over 6°S-6°N; the average across all LOP cases is first subtracted out, to remove the influence of the tilt effect. Only values in the western Pacific (west of 200°E) are plotted. Positive values indicate westerlies. While only four LOP cases are shown here, a deeper thermocline (as indicated by warmer temperature) in the western Pacific is accompanied by a westerly wind stress anomaly (and vice versa) for all LOP cases.

Extended Data Figure 7. An intermediate coupled model (ICM) with imposed distance effect annually-varying wind forcing generates a cold tongue annual cycle. All fields as shown are averaged over 6°S-6°N. **(a)** Distance effect zonal wind anomalies from the lowest model level of the CESM 1.2 coupled to a slab ocean (contour interval 0.75m/s, dashed contours are negative, zero contour omitted) and the SST response of the ICM to the applied wind forcing (shaded). This shows the cold tongue annual cycle in SST generated by the winds. **(b)** Full zonal wind (CESM 1.2 slab ocean + ICM) anomalies up to 200°E (shaded) and ICM thermocline depth anomalies east of 170°E (contour interval 2m, dashed contours are negative, zero contour omitted). This shows the connection between the winds and the cold tongue through thermocline changes. **(c)** SST anomalies due to the distance effect orbital forcing in the CESM 1.2 coupled to a slab ocean, showing the peak warming around December from the thermodynamic response to the distance effect insolation. The magnitude of the SST change here is not directly comparable with that of the ICM in panel (a), because of the lack of ocean dynamical feedback in the slab ocean that would alter the thermodynamic SST response. See [Methods](#) for details.

Extended Data Figure 8. Seasonal longitudinal shift in the Walker circulation due to the distance effect. The difference between the distance-only run and zero annual forcing run (former minus latter) for various climate fields averaged over March-June (following aphelion) in the left column, and September-December (following perihelion) in the right column. **(a-b)** Precipitation (shaded) and wind stress (vectors). **(c-d)** Zonal overturning circulation at the equator displayed as vectors, with the x-component being the divergent component of the zonal

wind (in m/s) averaged 10°S-10°N and y-component being the pressure vertical velocity (in Pa/s) multiplied by 250, also averaged 10°S-10°N. The green bar in (c-d) indicates the approximate longitudes of the Maritime Continent. **(e-f)** 200mb velocity potential. **(g-h)** Surface pressure. The precipitation in panels (a-b) show a shift in the location of equatorial rainfall between the Maritime Continent and western equatorial Pacific between March-June and September-December, associated with changing equatorial trades over the western equatorial Pacific. The zonal overturning circulation in panels (c-d) show anomalous subsidence over the Maritime continent and anomalous uplift over the western equatorial Pacific in March-June, indicating an eastward shift in the main uplift region of the Walker circulation; the opposite occurs for September-December. The velocity potential change in panels (e-f) shows a predominantly zonal wavenumber 1 pattern with the nodal point over the Maritime continent, reversing in sign between March-June and September-December. The surface pressure change in panels (g-h) show a see-saw in atmospheric mass between Africa/Indian ocean and the Pacific, again with the nodal point at the Maritime continent. Thus, all fields shown are consistent with a seasonal longitudinal shift of the Walker circulation towards the east in March-June and towards the west in September-December. The M_Map package⁴¹ is used to generate the maps, using coastline data from the Global Self-consistent, Hierarchical, High-resolution Geography Database⁴².

Extended Data Figure 9. Consistent cold tongue annual cycle changes between the iCESM 1.2 and CESM LOP simulations. Plotted is the climatological monthly mean SST averaged over 6°S - 6°N , for (top row) iCESM 1.2⁴⁰, and (2nd row) CESM LOP. The numbers on the top row denote the longitude of perihelion (where 90° = perihelion at winter solstice, 180° = at vernal equinox, 270° = at summer solstice, and 0° = at autumn equinox), and the last column from simulations setting eccentricity to zero. To facilitate comparison, an offset is added to each panel so that the annual mean SST averaged over 145 - 275°E is the same as for the observational data as shown in [Extended Data figure 1a](#), 27.44°C . Despite the short integration time for the CESM LOP, the cold tongue seasonal cycle changes are qualitatively similar with the longer iCESM 1.2 simulations
